Gatzoulis et al. in 1995 provided the first clues to a potential etiology for ventricular arrhythmias in rTOF. They reviewed the clinical data on 178 adult survivors with rTOF (mean follow-up 21.4 years). Nine patients were found to have sustained ventricular arrhythmias and four patients had postoperative SCD. Holter monitor data, electrocardiograms (ECGs), chest x-rays (CXRs), and Doppler echocardiographic data were included in the analysis comparing those with versus without sustained ventricular arrhythmias/SCD. They found that QRS duration ≥ 180 ms was 100% sensitive to predict sustained ventricular arrhythmias and SCD, and that QRS duration correlated with RV size (100) (Fig. 68.19).

Figure 68.19. Plot of QRS duration in 182 patients. Those with syncope and VT (squares) and sudden death (triangles). QRS duration ≥ 180 ms was 100% sensitive in predicting sustained VT and syncope. (From Gatzoulis MA, Till JA, Sommerville J, et al. Mechanoelectrical interaction in tetralogy of Fallot; QRS prolongation relates to right ventricular size and predicts malignant ventricular arrhythmias and sudden death. *Circulation* 1995;92:231–237, with permission.)

Figure 68.20. Actuarial probability of sudden cardiac death-free survival after surgical treatment of tetralogy of Fallot. (From Silka MJ, Hardy BG, Menashe VD, et al. A population based prospective evaluation of risk of sudden cardiac death after operation for common congenital heart defects. *J Am Coll Cardiol* 1998;32:245–251, with permission.)

Over the next few years, there was an emergence of data suggesting that the SCD risk in rTOF was a time-related risk factor that accelerated after 20 to 25 years after surgical repair. Silka et al. demonstrated that the risk of developing SCD in rTOF was close to 100 times greater than the general population and the risk became apparent 20 years after repair (Fig. 68.20). Nollert et al. (101) found that the risk for SCD was 0.27% per year for the first 25 years post repair but accelerated to 0.94% per year after 25 years ($p = 0.003$) (Fig. 68.21).

Long-term postoperative PI with progressive RV enlargement and dysfunction were the anatomic and physiologic correlates that began to explain the time-related risk of SCD and the relationship between RV size and QRS duration. PI leads

Figure 68.21. Long-term survival after correction of tetralogy of Fallot. All patients who died within the 1st year after correction were excluded for calculation of long-term survival. The curve shows two different phases that are distinct. The early, low-risk phase lasts 25 years; thereafter, the risk increases significantly. Mortality risk (r) per year, as a linearized number, is calculated for each phase. (From Nollert G, Fischlein T, Bouterwek S, et al. Long-term survival of patients with repair of tetralogy of Fallot: 36-year followup of 490 survivors of the first year after surgical repair. *J Am Coll Cardiol* 1997;30:1374–1383, with permission.)

Figure 68.22. Proposed relationship between PI, RV size, and QRS duration over time following TOF repair. Risk of SCD related to duration of 180 ms. PI, Pulmonary insufficiency; RV, right ventricle; RBBB, right bundle branch block.

to progressive RV enlargement and eventually RV systolic dysfunction. The QRS, although widened from a right bundle branch block pattern since repair, lengthens with time to eventually reach the risk-related duration of 180 ms (Fig. 68.22).

Ventricular tachyarrhythmias, including sustained monomorphic VT and SCD, can occur early after surgery or years after intracardiac repair of TOF. The risk factors associated with ventricular tachyarrhythmias and SCD appear multifactorial in origin consisting of several clinical risk factors including older age at repair, male sex, severe heart failure as assessed by New York Heart Association (NYHA) classification, and repair via a right ventriculotomy rather than atriotomy (102).

With the recognition of PI as the culprit hemodynamic lesion in rTOF, many studies have evaluated the outcome following PVR, investigating the change in functional class, RV size and function, and the risk for VT and SCD. Prior studies have demonstrated that following PVR, NYHA functional class improves (103) (Fig. 68.23).

Over the years, echocardiography has provided useful information in the diagnosis and long-term management of patients

Figure 68.23. Bar graph demonstrating New York Heart Association (NYHA) functional class pre and post-pulmonary valve replacement for PI in repaired tetralogy of Fallot. Functional class of patients was improved significantly; preoperatively, 76% of patients were in NYHA class III-IV, and after pulmonary valve replacement, 97% of surviving patients were in class I-II ($p = 0.0001$).

with rTOF; however, advances in CMR have provided accurate and reproducible measurements of the RV size and function and can now be used to predict major adverse clinical outcomes late after TOF repair. CMR has already demonstrated that there is a threshold of right ventricular dilation beyond which restoration of normal right ventricular systolic function cannot be achieved with pulmonary valve replacement, leading to appropriate risk stratification and therapeutic interventions. Knauth et al. determined independent predictors for major adverse clinical outcomes (death, sustained VT, and worsening NYHA functional class to III or IV) late after rTOF. They found that 20.5% adverse outcomes occurred over a median follow-up period of 4.7 years. Predictors for poor outcome included late repair (≥ 6 years old), increased RV end-diastolic volume, reduced RV and LV ejection fraction, and longer QRS duration. Additionally, there was 100% sensitivity for adverse clinical outcome when the RV end systolic volume was ≥ 45 mL/m², and 96% specificity when the right ventricular ejection fraction (RVEF) $< 30\%$ (104).

RV volume decreases following PVR for severe PI. Vliegen et al. (105) demonstrated with CMR that the RV end-diastolic and systolic indexed volumes decreased following PVR. However, RVEF did not significantly change (Fig. 68.24). Therrien et al. also evaluated RV size and function following PVR for PI in rTOF. She and her colleagues demonstrated that when the RVEF was $\geq 40\%$ pre-PVR, 50% maintained an RVEF $\geq 40\%$ at follow-up, compared to those with preoperative EF $< 40\%$, where only 13% were able to achieve an EF $> 40\%$ at follow-up (106).

Therefore, the exact timing of when to perform PVR in adult patients with rTOF continues to evolve. Timing is a balance between removing the regurgitant volume and therefore improving RV size and possibly improving or maintaining systolic function, and eventual valve failure and need for reintervention following PVR. Geva recommended PVR when regurgitant fraction $\geq 25\%$ (moderate to severe insufficiency) and at least two of the following objective criteria in asymptomatic patients were observed:

RV end-diastolic volume index >150 mL/m² or Z-score >4

- RV end-systolic volume index >80 mL/m²
- RVEF $< 47\%$
- LV ejection fraction $< 55\%$
- Large RVOT aneurysm

Figure 68.24. Ventricular volumes before and after pulmonary valve replacement in 26 patients. Note the significant decrease of right ventricular volumes in contrast to the unchanged left ventricular volumes. (From Vliegen HW, Van Straten A, de Roos A, et al. Magnetic resonance imaging to assess the hemodynamic effects of pulmonary valve replacement in adults late after repair of tetralogy of Fallot. *Circulation* 2002;106:1703–1707, with permission.)

- QRS duration >140 ms
- Sustained tachyarrhythmia related to right heart volume load
- RVOT obstruction with RV systolic pressure $\geq 2/3$ systemic
- Severe branch PA stenosis not amenable to transcatheter therapy
- \geq Moderate tricuspid regurgitation (TR)
- Residual left-to-right shunts with pulmonary-to-systemic flow ratio ≥ 1.5
- Severe AR
- Severe aortic dilatation (diameter ≥ 5 cm)

PVR was indicated in symptomatic patients with rTOF fulfilling ≥ 1 of the quantitative criteria detailed above (107).

Though surgical PVR had remained the procedure of choice for several years, the first successful human percutaneous pulmonary valve implant was performed by Bonhoeffer et al. (108) in a patient in 2000. Since there have been significant advances in transcatheter therapies directed toward PVR (see Chapter 13), with encouraging success rates. Initial studies have demonstrated marked improvements in right ventricular pressure, RVOT gradient, pulmonary regurgitation, and MRI-defined ventricular indices as well as pulmonary regurgitation, and improvement in both subjective and objective exercise capacity (109).

Finally, does the risk for VT/SCD improve following PVR? Therrien et al. evaluated ECG changes and risk for VT and SCD following PVR for severe PI in rTOF. Seventy patients with a mean age of 28.2 years underwent PVR with follow-up at a mean of 4.7 years. They found that the QRS duration stabilized but did not decrease, and the incidence of monomorphic VT decreased from 22% to 9%. Nine patients underwent intraoperative cryoablation for VT and at 5 years follow-up had 100% freedom from recurrent VT whereas the nonablation group had only a 68% freedom from VT (110).

Still, despite the advances in CMR to better define RV size and function along with the severity of PI, the data on QRS duration, and the success achieved with PVR, clinicians evaluating and treating those with rTOF continue to struggle with risk stratification for SCD of rTOF patients. Khairy et al. through a multicenter trial found that programmed ventricular stimulation predicted those who subsequently developed VT and SCD. Both inducible monomorphic VT, relative risk of 5.0, and polymorphic VT, relative risk of 12.9, predicted future clinical VT and SCD (111) (Fig. 68.25).

PI leading to RV enlargement and systolic dysfunction continues to be the most common problem facing this population and evidence suggests that this leads to QRS prolongation and risk for SCD. Programmed stimulation may also help to differentiate those at risk and PVR along with VT mapping. Intraoperative cryoablation seems to provide the best risk reduction for SCD. As risk factors for SCD in rTOF become reproducible and agreed upon, the next era will evaluate those who would benefit from primary prevention with intracardiac cardioverter defibrillators.

Although VT and SCD continue as the most worrisome of long-term issues for the rTOF patient, other problems may arise including

1. Atrial arrhythmias; almost one third of those with rTOF develop atrial fibrillation, flutter, or SVT (112).
2. Branch PA stenosis; there are no consensus guidelines on the indication to intervene upon branch PA stenosis in rTOF. Balloon angioplasty and/or stenting of a branch PA may be considered when the RV pressure is $>50\%$ of the systemic level or at lower pressure when there is RV dysfunction. Transcatheter interventions may also be considered when there is unbalanced pulmonary blood flow or otherwise unexplained dyspnea with severe vascular stenosis (66). Anatomic narrowings of the PAs are common

Figure 68.25. A: Kaplan-Meier curve of event-free survival according to results of programmed ventricular stimulation. B: EP indicates electrophysiologic; SMVT, sustained monomorphic VT; and SPVT, sustained polymorphic VT.

(Fig. 68.26) in this patient population; however, the indication to proceed with transcatheter or surgical repair is currently unknown.

3. Aortic root dilation; more recently it has been found that adults with rTOF have significant aortic root dilation that appears to be related to abnormal aortic wall structure. Tan et al. found that the aortic root diameter was greater than expected and that intrinsic aortic wall abnormalities exist from infancy into adulthood. This therefore suggests a potential cause and effect relationship leading to aortic root dilation (113) (Fig. 68.27). Recently, case reports for the first time have described aortic root dissection in patients with rTOF and severe aortic root enlargement (114).

In summary, the pathophysiology of rTOF is complex and the patient carries several cardiovascular concerns into adulthood that are unique to their anatomy and often their surgical repair. Over time, the risks of ventricular dilation and dysfunction, exercise intolerance, heart failure, arrhythmias, and risk for sudden death increase, though overall the long-term outcome of patients after TOF repair is excellent, with estimated 20-year survival rates of over 90%. Patients should be followed on a routine basis with CMR for RV size and function, degree of PI, branch PA stenosis, and aortic root size. Routine ambulatory monitoring and ECGs should also be performed. Eventually, with improvements in both diagnostic and percutaneous intervention capabilities, patients requiring PVR with even differing RVOT morphologies may become candidates for transcatheter PVR (115).

D-Transposition of the Great Arteries

The hallmark of D-transposition of the great arteries (TGA) is ventriculoarterial discordance, in which the aorta arises from the RV and the PA arises from the LV. The atrial switch repair was first described by Senning in 1959 and later by Mustard in 1964 to route the systemic venous blood flow (“baffled”) to the mitral valve and the “pulmonary” LV, and the pulmonary venous blood flow is routed to the tricuspid valve (TV) and the “systemic” RV. A postoperative population of patients who have undergone atrial switch (Mustard, Senning) procedures for D-TGA has emerged over the years. The majority of such patients will do well for a number of years but with time, they are at risk for a number of concerning problems.

1. Arrhythmias—atrial and ventricular tachyarrhythmias, heart block
2. Baffle obstruction—systemic and pulmonary venous obstruction
3. Systemic (right) ventricular failure
4. Systemic (tricuspid) AV valve regurgitation,
5. SCD.

Arrhythmias

Patients who have undergone an atrial switch operation (e.g., Mustard or Senning operations) are rarely exclusively in sinus rhythm a decade after repair, suffering from either atrial or ventricular arrhythmias. There is little doubt that these arrhythmias relate directly to the extensive suture lines created during atrial baffling, because the problem has largely disappeared in patients who were managed with the later arterial switch operation (ASO) (116). The overall incidence of arrhythmias in the population of D-TGA s/p atrial switch is not known but appears in most studies to be one of the highest-risk lesions/repairs leading to clinically significant arrhythmias. In a large Dutch registry of over 5,000 ACHD

Figure 68.27. (A,B) are from a normal child. (C,D) are from a case of TOF aged 20 months. (C) shows disruption of the elastic lamellae, and (D) shows increase in fibrous tissue (*green*). (A,C) are stained in elastic van Gieson and (B) and (D) in trichrome. E: cardiovascular magnetic resonance imaging of a 26-year-old patient with repaired tetralogy of Fallot demonstrating generalized enlargement of the ascending aorta measuring 5.5 cm.

patients, D-TGA/atrial switch patients had a 35% prevalence of atrial arrhythmias (second only to single-ventricle patients) and 7% prevalence of ventricular arrhythmias (second only to TOF) (54). Gelatt et al. found a 14% incidence of atrial flutter and only 40% in sinus rhythm after 20 years, whereas Wilson et al. found a higher incidence of losing sinus rhythm over time with only 18% in sinus rhythm 15 years after repair (117–119) (Fig. 68.28).

SCD is the most common cause of late mortality in patients with TGA and atrial switch (Mustard or Senning) with an actuarial incidence approaching 10%, 20 years after surgery (3). Unfortunately, SCD remains the most concerning unpredictable event in the post-atrial switch D-TGA patient; however, identifying a high-risk group has been difficult. Main associated features are severe systemic ventricular dysfunction and history of

atrial tachyarrhythmias. Importantly, supraventricular arrhythmias often precede or coexist with VT, suggesting that they are important triggers for fatal events (119–123). Multiple studies have demonstrated this higher than expected incidence of SCD with no consistent risk factors (3,117). Some studies suggest that atrial arrhythmias are the culprit arrhythmia leading to SCD (124). Silka et al. (3) found that the risk for SCD with D-TGA/atrial switch began shortly after repair as opposed to other CHD lesions, such as TOF, where the risk is not significantly realized until 15 to 20 years postrepair (Fig. 68.29).

Ultimately, many patients will require pacemaker therapy as a result of sinus node dysfunction or symptomatic bradycardia. However, a thorough anatomic assessment for residual baffle leaks and/or obstruction should be performed prior to pacemaker lead placement. Transvenous intracardiac lead

Figure 68.28. Cumulative actuarial curves showing loss of sinus rhythm.

placement and obtaining adequate thresholds can be difficult in these patients and require knowledge of complex CHD anatomy (Fig. 68.30) (Chapter 13).

Tachyarrhythmias can be treated with either radiofrequency ablation or antiarrhythmic therapy. Because of the apparent sick sinus syndrome associated with this lesion, caution must be exercised when utilizing antiarrhythmic medications. Radiofrequency ablation in this population is challenging, secondary to the complex anatomy, multiple areas of scar, and large amounts of patch material. The success of ablation for tachyarrhythmias is approximately 70%, therefore less than expected for those with normal anatomy (125). The indication for implantable cardioverter defibrillator therapy remains secondary prevention.

Figure 68.29. Actuarial probability of sudden cardiac death (SCD)-free survival after surgical treatment of tetralogy of Fallot (TOF) and D-transposition (D-TGA). Note the early accumulation of SCD following repair for D-TGA as compared to the risk with TOF occurring 20 to 25 years after repair.

Baffle Obstruction and Leaks

Baffle obstruction is an infrequent but serious complication following the atrial switch repair. Systemic venous obstruction is much more common after the Mustard compared to the Senning operation. When encountered, it commonly involves the superior vena cava (SVC) rather than the inferior vena cava (IVC), though both may be clinically silent and though significant stenosis in either can present with either SVC syndrome in the former and hepatic congestion and/or cirrhosis with edema in the latter. Wilson et al. (119) discovered baffle obstruction requiring

Figure 68.30. Pacemaker therapy for D-transposition/atrial switch. **A:** Atrial lead must travel from the superior vena cava through the systemic venous baffle to the remnant left atrium/atrial appendage. The ventricular lead continues across the mitral valve and is fixed within the left ventricle. **B:** Chest radiograph showing final positioning of the pacemaker leads.

Figure 68.31. Systemic venous baffle obstruction in D-transposition/atrial switch. **A:** Diagram demonstrating the typical location of systemic venous baffle obstruction. **B:** Moderate narrowing typically seen in this population. **C:** Severe obstruction of the SVC as it enters the systemic venous baffle.

reoperation in 6/113 (5%) patients. In an additional 5%, sudden death was related to baffle obstruction following the Mustard operation. In this long-term study spanning 28 years, there were 19 deaths overall and 50% were related to baffle obstruction. Other studies have not found this association. Nevertheless, how to define baffle obstruction is open for debate. Most will have narrowing at the junction between the SVC and the systemic venous baffle as it bends anteriorly and leftward (Fig. 68.31).

Doppler echocardiography, particularly transesophageal imaging, may detect obstruction; however, limitations still exist. CMR has become the gold standard for the evaluation of baffle obstruction (see Chapter 10). The indication for relief of obstruction is not clear. Whether intervention should be based upon one or several factors is not known.

1. Percent narrowing compared to normal SVC
2. Pressure gradient
3. Symptoms (extremely rare), or
4. Planned intervention such as placing pacing wires across the narrowed segment.

Clearly, placing pacing wires across the narrowed segment will increase the likelihood of causing complete obstruction (Fig. 68.32). Percutaneous delivery of balloon expandable stents have been deployed for systemic venous baffle obstruction and found to be safe and effective in limited follow-up

(126,127). General guidelines for SVC baffle obstruction include the following:

- Angiography of the SVC prior to placing pacing wires across the systemic venous baffle. If there is significant narrowing (>50% normal SVC, pressure gradient by cardiac catheterization, systemic venous collaterals secondary to obstruction), SVC stent therapy should be performed prior to placing pacing wires. (see Chapter 13)
- Patients with SVC syndrome (upper extremity/body edema) should undergo cardiac catheterization and stent therapy.
- Patients with mild narrowing without hemodynamic gradient with no need for pacing wires can be observed.

Pulmonary venous baffle obstruction may also occur but less frequently. It is rare after both the Senning and Mustard procedures, but is a serious complication that may lead to PH requiring prompt attention. Transesophageal Doppler echocardiography or CMR will confirm the diagnosis (Fig. 68.33). Although balloon angioplasty can be performed, long-term complete relief is achieved with surgical repair.

BAFFLE LEAKS

Small leaks through the baffle are common but in our experience are rarely seen by transthoracic echocardiography

Figure 68.32. A 28-year-old patient with D-transposition/atrial switch s/p pacer placement now with essentially complete baffle obstruction (yellow arrow). Azygous runoff (white arrow) and multiple venous collaterals are present. The leads have been extracted. The patient underwent successful stent placement and the pacemaker leads were replaced.

(Fig. 68.34). Transesophageal echocardiography with bubble contrast will usually detect leaks from the SVC limb into the systemic venous baffle but may miss leaks around the inferior limb. These are more common than obstruction with an increased frequency in the Mustard population. They are usually small and hemodynamically insignificant but can pose a risk of paradoxical embolus or a cerebrovascular accident in the setting of tachyarrhythmias or transvenous pacemaker leads. Angiography from the SVC and IVC is the most sensitive imaging modality to detect small baffle leaks. Small leaks are hemodynamically insignificant and only pose a thromboembolic risk increased by pacing wires through the baffle, atrial arrhythmias, and atrial enlargement. In a multicenter study, Khairy et al. (128) found that transvenous pacing wires incur a greater than twofold increased risk of thromboembolic neurologic events with intracardiac shunts and that aspirin and coumadin did not provide protection.

Percutaneous baffle leak device closure is preferable over open heart surgery and cardiopulmonary bypass (127) (Fig. 68.35) (Chapter 13). Percutaneous closure should be considered when there is/are

- a significant left-to-right shunt with hemodynamic compromise
- systemic desaturation either at rest or with exercise (not related to PH)
- transvenous pacing wires either already in place or to be placed in the future and
- tricuspid valve regurgitation

Systemic AV valve (TV) regurgitation is present in most adult patients. On occasion, the TV maybe intrinsically abnormal, but more commonly the TR is secondary to annular dilation from

Figure 68.33. A 34-year-old patient with D-transposition/atrial switch presents with dyspnea on exertion. CMR demonstrates pulmonary venous baffle (PVB) obstruction (yellow arrow). RV, right ventricle.

Figure 68.34. D-transposition/atrial switch with a baffle leak. Ao, aorta; MPA, main pulmonary artery; SVC, superior vena cava; SVB, systemic venous baffle; IVC, inferior vena cava; PV, pulmonary veins; LV, left ventricle; RV, right ventricle.

Figure 68.35. Superior vena cava angiogram lateral projection in a 32-year-old patient with D-transposition s/p Mustard operation presents with cyanosis. **A:** demonstrates a large baffle leak (arrows) as contrast enters the pulmonary venous chamber. **B:** Now s/p NuMed Covered Cheatham Platinum stent to exclude the large baffle leak and relieve mild baffle stenosis. Pacemaker wires were extracted and then replaced following stent placement.

right ventricular enlargement. Mild to moderate TR is usually well tolerated. However, TV repair and/or replacement should be considered for those with severe TR to prevent worsening right ventricular function. In a single institutional study of 58 patients at a mean of 14 years following the Mustard operation, 60% had moderate and 2% had severe TR determined by Doppler echocardiography (129). Although the relationship between RV myocardial function and TR is not well defined, significant TR will exacerbate already impaired ventricular function and may contribute to exercise-related symptoms. Valvular repair should be considered when other cardiac surgery is being performed or in cases of severe TR in the face of right ventricular systolic dysfunction. Moons et al. (130) described the long-term outcome of patients who underwent Mustard or Senning repair for TGA in 339 patients in Belgium. TV regurgitation was shown to be positively correlated with worsening systemic ventricular function. Most patients had only trivial to mild TR (65.2%), 27.5% had moderate regurgitation, and 7.4% had severe regurgitation. Surgical TV replacement was performed in four patients and annuloplasty in one. Severe regurgitation was more prevalent in the Senning (9.2%) than the Mustard (3.2%) cohort (130).

Systemic (Right) Ventricular Dysfunction

Progressive right ventricular enlargement and worsening systolic function after atrial switch operations can develop, often resulting from the systemic workload placed on the

morphologic RV. Right ventricular dysfunction will occur in approximately 15% of patients by the second to third decade of life (119,131). In contrast, clinical right ventricular failure is unusual occurring in only 2% of patients up to the third decade of life and rarely is the cause of death. Ross-Hesselink et al. performed a prospective study of young adults to evaluate systemic right ventricular function 25 years after repair. Initially, patients demonstrated good right ventricular function. However, over half (61%) demonstrated moderate-to-severe dysfunction after 25 years of follow-up (132). Although applying heart failure pharmacologic regimens to those with a systemic RVs and systolic dysfunction seems reasonable and intuitive, there are no convincing data to support this practice. Most patients are typically placed on ACE inhibitors for afterload reduction and it would seem that the possible benefit to risk ratio favors this practice. However, studies have not proven that ACE inhibitors do in fact provide benefit in exercise ability or right ventricular indices (133). Caution must be used with beta-blocker therapy in this population because of the risk for heart block in the face of conduction system disease.

Echocardiography provides a qualitative assessment of RV function but lacks details of accurate volume assessment and EF to follow patients long term. Tissue Doppler evaluation may provide important information regarding RV diastolic function and contractility. CMR has now become the gold standard for the evaluation of right ventricular size and function (Fig. 68.36) (96,134).

Figure 68.36. Cardiovascular magnetic resonance imaging (CMR) of a 32-year-old patient with D-transposition/Mustard. CMR has become the gold standard to assess right ventricular size and function. Ao, aorta; LV, left ventricle; PA, pulmonary artery.

Figure 68.37. Intracoronary ultrasound image of a normal coronary artery segment (A) and anterior descending segment (B) with intimal proliferation comprising 180° of the vessel circumference (arrows indicate intimal thickening).

Late-Stage Ventricular Failure

In patients who develop late systemic ventricular failure after atrial switch, surgical intervention with either cardiac transplantation or anatomic correction (arterial switch) should be considered. To achieve successful ASO it requires “training” of the LV. PA banding is performed to train the LV and create LVH prior to arterial switch. With PA banding, the ventricular septum may shift toward the RV and decrease the tricuspid regurgitant volume by improving leaflet coaptation (135). Although this staged surgery has been successfully performed at a few centers (136,137), adult patients have significant problems progressing to the second stage after banding. Poirier et al. (138) found that in a series of 35 patients, 10 failed LV training and was common in those >12 years old.

Arterial Switch for D-TGA

ASO, originally performed in 1975, has become the standard corrective procedure for patients with D-TGA who do not have significant left ventricular outflow obstruction (139). Excellent long-term outcomes after ASO of >95% survival at 20 years following discharge have been reported from several centers (140,141).

In the next decade, a number of adults who survived neonatal arterial switch will reach adolescence and young adulthood. Theoretically, patients should do well with successful surgery; however, the long-term effects of this operation are not known. The former pulmonary valve (the neo-aortic valve) is not symmetrically formed in transposition (142), and its long-term competency will require ongoing assessment. The coronary arteries that were reimplanted in the infant may or may not be normal in the future.

Exercise electrocardiography (with subsequent confirmation at cardiac catheterization) has identified obstructive coronary ostial disease in a small percent of patients (143). Patients with myocardial ischemia after the arterial switch may not experience typical angina due to denervation of the heart as the great arteries are transected (144). It is also not known how coronary disease in such patients may accelerate in the future and whether they should be treated with antiplatelet or lipid-lowering agents. Additionally, we still do not know the best imaging modality to follow these patients. These patients will more than likely require serial evaluations with stress imaging (echocardiography, nuclear or CMR) for coronary obstructive disease and ischemia. There have been reported cases of myocardial ischemia and even infarction status post the ASO (145).

Hutter et al. (146) from the Netherlands reviewed the long-term outcome of children undergoing arterial switch for D-TGA. Outcomes of 151 patients demonstrated pulmonary

stenosis as the most common cause for reintervention, and there were two late deaths (PH and coronary artery disease with ventricular fibrillation). Sixty-one patients underwent coronary angiography and four patients had significant coronary pathology: occluded left anterior descending coronary artery in two, occluded right coronary artery in one, and stenosis of the right coronary in one (146). Pedra et al. (147) reviewed 20 asymptomatic arterial switch patients for coronary artery disease with intravascular ultrasound. Almost 90% of the vessels imaged had some degree of coronary atherosclerosis with 30% being severe (147) (Fig. 68.37).

In conclusion, despite close medical and cardiac supervision, sudden death occurs in approximately 7% of patients (118,119) following atrial switch. To date, no specific risk factors have been identified that consistently predict a higher incidence of sudden death in this population. Specific attention to arrhythmias, both supraventricular and ventricular, the need for pacemaker therapy, right ventricular function, TV regurgitation, and baffle obstruction is necessary for optimal follow-up. Therefore, the young adult with D-TGA status-post surgical repair requires careful and thorough evaluation with detailed knowledge of the past medical, surgical, and transcatheter therapies. Routine testing should include a detailed history and examination, ECG, ambulatory Holter monitor, cardiopulmonary exercise testing, and noninvasive imaging with CMR, CCT, or echocardiography (if CMR not available or is contraindicated).

Congenitally Corrected Transposition of the Great Arteries

The natural history of patients with congenitally corrected transposition of the great arteries (ccTGA) is largely dictated by the function of the systemic RV and by the presence or absence of associated abnormalities. Patients with ccTGA may not present for diagnosis until adolescence or adulthood. However, the majority of patients will have associated abnormalities—VSD (70%), pulmonary and subpulmonary stenosis (40%), abnormalities of the systemic (tricuspid) valve (90%), and complete heart block (2% per year)—that may permit early diagnosis.

In the largest single-institution study to date, Connelly et al. reported the clinical findings in 52 adult patients with ccTGA. Thirteen (25%) of the patients died at a mean age of 38 years. The most common causes of death were progressive heart failure and sudden death accounting for 70% of the mortality in this series. Arrhythmias were common with almost 50% of the patients requiring pacemaker therapy for complete heart block, and 38% of patients demonstrated atrial arrhythmias (atrial fibrillation, atrial flutter, and SVT). Moderately severe and severe systemic (tricuspid) valve regurgitation developed in 26% of the survivors. Surgical intervention was necessary

in 70% of patients. Systemic (right) ventricular function was reduced compared to controls (43% vs. 58%) and did not augment with exercise (148). The combination of poor ventricular function and systemic AV valve regurgitation appears to be a marker of poor outcome.

Patients with ccTGA have a 2% per annum risk of developing complete heart block. There is also a risk of tachyarrhythmias, both reentry type arrhythmias related to the abnormal conducting system anatomy or to accessory pathways and atrial and VTs that may all contribute to worsening systemic ventricular function. In the context of the systemic RV, chronic ventricular pacing may further negatively impact its long-term ventricular function (149).

SYSTEMIC VENTRICULAR FAILURE IN CONGENITALLY CORRECTED

TRANSPOSITION OF THE GREAT ARTERIES

Many patients do very well with a systemic RV with uncomplicated ccTGA into early adulthood; however, the rarity of this condition limits experience at a single center. A multicenter retrospective study by Graham et al. demonstrated that the time-related progressive decline in systemic ventricular function risk factors for progression included associated defects and prior open heart surgeries. In this study, one-third of patients without associated lesions developed heart failure by the fifth decade, and two-thirds of patients developed heart failure by 45 years of age when associated defects were present (150).

Such patients, though often asymptomatic, need to have objective evaluation of their functional capacity. This was highlighted by Fredriksen et al. publishing their results of cardiopulmonary exercise testing in a group of 41 adult patients from Toronto. They showed a notably reduced maximal oxygen uptake of 22 mL/kg/min in the 19 to 29 year age group and 21 mL/kg/min in the 30 to 39 year age group (both were approximately half that of normal controls). In the 40 to 55 year age group this significantly dropped to 11 mL/kg/min. The reasons for this are multifactorial, but important factors include impaired ventricular function, limited chronotropic response to exercise, and abnormal lung function, particularly in patients who had previous surgery (151).

Systemic AV valve regurgitation plays a significant role in worsening systemic ventricular function (152). Similar to the approach for MR and left ventricular systolic dysfunction, the TV should be considered for repair or replacement when ventricular function worsens in the face of moderate or severe regurgitation, rather than waiting for a decline in functional status. Late referrals for TV replacement may predict a poor surgical outcome. Beauchesne et al. demonstrated that preoperative RVEF was the only marker for poor survival. Therefore, TV replacement must be considered early when there is severe regurgitation with either RV systolic dysfunction and/or heart failure symptoms (153).

Systemic AV valve replacement is not without risk but can be performed with acceptable outcomes. At the Mayo clinic, 40 patients underwent systemic AV valve replacement for severe regurgitation. The preoperative RVEF was 20% to 60% (mean 48%). In-house mortality was 10% and another eight patients died during follow-up. Overall survival was 78% at 5 years and 61% at 10 years. Systemic ventricular failure was the cause of death for all patients in this series. Survivorship correlated with preoperative RVEF > 44%, therefore emphasizing the need for early systemic AV valve replacement in this population (154).

The double switch operation remains an option for those who develop systemic ventricular failure as an alternative to cardiac transplant. The procedure restores the LV to the systemic position and therefore the physiology and the

Figure 68.38. Congenitally corrected transposition of the great arteries and heart diagram following double switch procedure. Initial pulmonary artery banding is not shown. This is followed by atrial switch and arterial switch so that the physiology is correct and the systemic circulation is supported by the morphologic left ventricle. RV, right ventricle; LV, left ventricle; RV, right ventricle; Ao, aorta; PA, pulmonary artery.

anatomy are corrected. The LV must be “trained” to handle the systemic circulation by banding the PA, raising LV pressure, and promoting hypertrophy. This would also be the appropriate surgical opportunity to repair or replace the systemic AV valve. Once the LV is prepared and functioning at systemic circulation, a combined atrial switch and an ASO is performed (Fig. 68.38). Therefore, the venous return through the baffle is directed to the anatomically and physiologically correct ventricle and the ventricular–arterial concordance is completed with the arterial switch. Langley et al. described the outcome in a cohort of 54 children and adults (mean age 3.2 years) with ccTGA undergoing the double switch procedure. The surgical mortality was 5.6% and there were two late deaths. Of those with preoperative advanced TR, two died early, two died late, and one underwent transplant (155). Despite these results, LV dysfunction is more common in older patients, and the incidence of atrial arrhythmias would statistically increase following atrial baffle. Overall comparison with long-term data of aggressive heart failure management, cardiac transplantation, and double switch operation is necessary to determine the best approach in the adult patient.

In conclusion, patients with ccTGA represent a rare and complex group for whom outcomes have traditionally been largely dependent on function of the systemic RV. Although this lesion may seem fairly benign in the asymptomatic adult patient, clearly, survival is limited and multiple associated abnormalities may occur requiring close medical supervision. Adult patients should undergo routine exams, ECG, 24-hour ambulatory monitoring, and an assessment for valvular disease. The evaluation of systemic ventricular function can be difficult due the geometry of the RV. Similar to D-TGA, echocardiography may provide qualitative assessment of RV size and function; however, accurate assessment of RV volumes and EF is best assessed with CMR (Fig. 68.39) (156). Those with pacemakers need radionuclide angiography (104) or cardiac CT (157).

Figure 68.39. Cardiovascular magnetic resonance imaging of a 36-year-old patient with congenitally corrected transposition of the great arteries. **A:** Four-chamber view, note the left atrium to the enlarged right ventricle (RV) supporting systemic circulation. **B:** Sagittal two chamber view showing an enlarged systemic RV.

SINGLE VENTRICLE

Many complex cardiac malformations are characterized by the existence of only one functional ventricle, which has to maintain both systemic and the pulmonary circulations. Single-ventricle anatomy and surgical options are detailed elsewhere (see Chapter 52).

Unrepaired young adult patients with a univentricular heart have a poor prognosis. In a series of unoperated patients with various forms of univentricular anatomy, ($n = 83$), 70% died before 16 years of age with left ventricular anatomy, and 50% died 4 years after the diagnosis when the RV was the systemic ventricle. In this study, the most common causes of death were arrhythmogenic, heart failure, and SCD (158). Anatomic and physiologic factors that support extended survival in the unoperated univentricular heart include (159)

- Double inlet LV with transposed great vessels
- Pulmonary stenosis
- Normal LV systolic function and
- \leq mild AV valve regurgitation

Cyanotic Adult

Multiple medical problems occur as a result of chronic cyanosis. These are both a factor of chronic hypoxia to vital organs and hyperviscosity. The hematologic manifestations include thrombocytopenia, erythrocytosis, thromboemboli, iron deficiency, and bleeding complications. It seems paradoxical that cyanotic patients may suffer thromboembolic events but develop bleeding issues as well. Embolic events are from derangements in the coagulation pathway whereas bleeding diatheses are secondary to platelet dysfunction and thrombocytopenia (68). Thus, there is no agreement as to whether cyanotic patients should receive antiplatelet agents or systemic anticoagulation. The decision to initiate aspirin or coumadin therapy is individually based and many times driven by a documented thromboembolic event or discontinued after a clinically significant bleeding episode, for example, hemoptysis.

Patients may develop hyperuricemia from decreased absorption of uric acid and may lead to gout, urate nephropathy, and nephrolithiasis. Renal disease is also common from hypoperfusion and chronic hypoxia. Neurologic events include cerebral abscesses, hemorrhage, and thromboemboli from right-to-left intracardiac shunting. Therefore, air filters should always be placed on intravenous lines to prevent paradoxical air embolization. Hyperviscosity symptoms from polycythemia occur at various levels of hematocrit, with no level being an exact cut-off for symptoms. Symptoms may include headache, dizziness, fatigue, dyspnea, mental status changes, and paresthesias. Symptoms may be exacerbated at lower levels of hematocrit when iron deficiency is present. In this case, iron replacement is recommended (160).

The Fontan Patient

The Fontan operation places the systemic and pulmonary circulation in series, and is the treatment of choice for patients with a univentricular heart, resulting in near normalization of arterial saturation, and removal of the chronic volume overload. Patients who have undergone the Fontan procedure have now entered their fourth decade of life. In such patients, both the benefits and long-term sequelae associated with this palliation are often seen. Several late complications include arrhythmias, heart failure, exercise intolerance, ventricular dysfunction, thromboembolic complications, hepatic dysfunction, protein losing enteropathy (PLE), and worsening cyanosis (161).

The Fontan circulation is dependent upon some degree of systemic venous hypertension at the expense of pulmonary hypoperfusion. This hemodynamic derangement, along with multiple prior surgeries, extensive suture lines and intracardiac scarring, chronic cyanosis for a period of time, all contribute to potential complications in the adult patient that are listed below.

- Arrhythmias
- Thromboemboli from enlarged hypocontractile right atrium in classic Fontan circuit (Fig. 68.40). Paradoxical emboli are possible with residual right-to-left shunts.
- Protein losing enteropathy

Figure 68.40. Transesophageal echocardiogram of the right atrium (RA) in a 23-year-old patient with tricuspid atresia, s/p classic Fontan procedure. Image demonstrates an enlarged RA with a clot (arrow) attached to the wall of the RA. Note the heavy spontaneous contrast. The patient had persistent atrial arrhythmias and heart failure symptoms and subsequently underwent EC Fontan revision.

- Hepatic dysfunction
- Pulmonary vein compression
- Cyanosis
- Systemic venous collaterals
- Pulmonary arteriovenous malformations (AVMs)

Arrhythmias

After Fontan completion, arrhythmias can result from multiple etiologies including dysfunction of the sinus node, increased atrial pressure, and the presence of suture lines and scars with the incidence of atrial tachy- and bradyarrhythmias increasing with time. Data from the Netherlands found atrial arrhythmias in 50% of their adult Fontan patients (162). In this population, atrial arrhythmias were frequently resistant. The mechanism for most are in the form of a macro-reentry circuit, many of which are multiple and complex. Radiofrequency ablative techniques are successful in >80%; however, recurrence is common and may be as high as 30% to 45% over the subsequent 6 to 12 months (163).

When atrial arrhythmias are detected, a complete hemodynamic evaluation for obstruction within the Fontan circuit should be pursued. The classic Fontan patient with “failing Fontan” criteria will tend to have a severely enlarged right atrium contributing to the medically resistant atrial arrhythmias and is frequently the indication for Fontan revision.

Previously, the incidence or presumed risk factors for SCD in patients with Fontan surgery has not been clearly defined. Khairy et al. (164) evaluated 261 Fontan patients to better define determinants of mortality in univentricular patients. Although the etiology appeared multifactorial, arrhythmias were likely responsible for the majority of sudden deaths (9.2%) when there was no other obvious cause. Other factors contributing to late deaths in this population included heart failure and thromboembolic complications.

Finally, completion of the extracardiac Fontan procedure (e.g., total cavopulmonary connection) for single ventricles avoids extensive suture lines in the right atrium, thereby reducing scarring and higher pressures that lead to intra-atrial reentry tachycardia and sinus node dysfunction. Extracardiac (EC) conduits and lateral tunnel (LT) Fontans are preferred today, and the Fontan conversion procedure (converting prior atriopulmonary Fontans to the EC or LT type) can be performed to reduce arrhythmia and thromboembolic events (93).

Thromboembolic Complications

Thromboembolic complications are a common source of morbidity with multiple clotting abnormalities reported in such patients, including decreased levels of protein C, protein S, and antithrombin III. Recently, clinical predictors for thromboembolic death included a lack of antiplatelet therapy or anticoagulant therapy and clinically diagnosed intracardiac thrombus. Though it is still unclear if all univentricular patients with Fontan palliation should receive antiplatelet or anticoagulation therapies, it is now recommended to give warfarin for patients who have a documented atrial shunt, atrial thrombus, atrial arrhythmias, or a thromboembolic event (36). Most centers will provide either antiplatelet or anticoagulation therapy to patients whom they consider at increased risk (164).

Protein-Losing Enteropathy

The presence of generalized edema, ascites, chronic pleural effusions, and diarrhea in an adult Fontan patient is highly suggestive of the diagnosis of protein-losing enteropathy. PLE

occurs in 3.7% of those with Fontan operation. The loss of a significant amount of protein via the gastrointestinal tract leads to symptoms of peripheral edema, fatigue, pleural and pericardial effusions, ascites, and chronic diarrhea (165). The etiology is not known but thought to be secondary to elevated systemic venous pressures. Other risk factors contributing to PLE include longer cardiopulmonary bypass times, heterotaxy syndrome, and ventricular anatomy other than a morphologic LV (166,167). Unfortunately, PLE bodes for a poor prognosis, with a 5-year survival of only 50% (165). There is no gold standard therapy as multiple case reports and small studies have described varying degrees of success. Current treatment strategies have included a high protein diet, afterload reduction therapy, inotropic agents, heparin, albumin infusion, octreotide, prednisone, and creation of an atrial fenestration (165,167).

Hepatic Complications Post-Fontan Surgery

In addition to the cardiac and hemodynamic disadvantages of Fontan circulation, there is a growing body of literature that has demonstrated that hepatic abnormalities may occur after the Fontan operation. These include coagulation disorders, cholestasis, liver fibrosis, and hepatomegaly with or without ascites (168,169). Baek et al. performed a cross-sectional study of 139 Fontan patients who underwent cardiac CT scans out of a total of 204 patients who had undergone the Fontan procedure between 1986 and 2003. Mean age was 19.0 ± 6.3 years and mean elapsed time since the initial Fontan operation was 11.5 ± 4.7 years. Fifty-seven patients had hepatic complications, including liver cirrhosis (25.9%), thrombocytopenia (7.2%), hyperbilirubinemia (20.9%), and hepatic masses (2.9%). Hepatic complications were significantly associated with ventricular dysfunction, absence of fenestration, thrombus in the Fontan tract, sinus node dysfunction, and tachyarrhythmia. Moreover, hepatic complications were correlated with the duration of Fontan circulation. Thus, the hepatic condition of patients who undergo the Fontan procedure should be regularly evaluated including non-invasive hepatic fibrosis markers and imaging modalities (170).

Cyanosis

Typically, systemic oxygen saturation in Fontan patient should exceed 94%. Etiologies for cyanosis include

- Residual surgically created fenestration
- Pulmonary arteriovenous malformations
- Systemic venous collaterals
- Baffle leaks—area where the Fontan circuit was sutured to native tissue

When cyanosis is found, some residual fenestrations may be seen with transesophageal echocardiography especially with echo contrast studies. Pulmonary AVMs, systemic venous collaterals, and most baffle leaks require angiography to make an accurate diagnosis. During catheterization direct agitated saline contrast to each PA along with transesophageal echocardiography can detect small vessel AVMs. Most causes of cyanosis can be treated with transcatheter device therapy (Fig. 68.41). In our practice, it is recommended that any patient who has Fontan circuit and cyanosis should undergo a diagnostic (often resulting in a therapeutic) cardiac catheterization. Cyanosis should be evaluated not only at rest but also with exertion.

Fontan Revision

The Fontan revision should be considered in those with a failing Fontan. This would include those with congestive

Figure 68.41. Lateral tunnel (LT) angiogram of a 33-year-old patient with tricuspid atresia s/p LT Fontan with fenestration. Patient presented to clinic with systemic saturation of 83%. **A:** demonstrates large residual shunt through the fenestration. **B:** LT angiogram following closure with a 18 mm Amplatzer septal occluder. A second defect was closure by the IVC. Saturation improved to 93%.

heart failure (dyspnea on exertion), recurrent and resistant atrial arrhythmias, persistent thromboemboli from low flow state, and poor kinetic energy through the Fontan circuit (Fig. 68.42). Surgery involves debulking of the enlarged right atrium, removal of any atrial thrombi, excision of right atrial scar tissue, epicardial pacemaker implantation, placement of an EC Gortex conduit from the IVC to the right PA SVC junction (EC Fontan), modified right atrial Maze procedure, and if documented atrial fibrillation, then left atrial Maze as well. The purpose of this revision is to improve cardiac output, reduce atrial arrhythmias, and prevent thrombus formation (171) (Fig. 68.43). Reported perioperative mortality rates for Fontan revision range from 2.4% to 6.7% with short-term follow-up revealing recurrent atrial arrhythmias in 13% to 30% (171–173). If recurrent atrial arrhythmias occur, vascular access for radiofrequency ablation is now more complicated with an EC circuit and requires transbaffle puncture.

Figure 68.42. Cardiovascular magnetic resonance imaging of a 23-year-old patient with a classic Fontan and symptoms of shortness of breath, and persistent atrial arrhythmias. The right atrium is enlarged with poor forward flow through the Fontan. The patient underwent Fontan revision.

Managing a univentricular patient remains a challenge, from the rare unoperated patient to those with failing Fontan circuits. Ultimately, the Fontan operation is a palliative procedure with resultant unique single-ventricle physiology with a high incidence of long-term complications. Adult patients with univentricular hearts and the Fontan physiology require careful, close, and routine follow-up.

Evaluation should be with specialized ACHD clinics including a detailed history and physical examination with particular emphasis on the type of prior surgical repairs, ECG, thorough noninvasive imaging (CMR, echocardiography, cardiac CT), and ambulatory Holter monitoring.

UNIQUENESS OF AN ADOLESCENT AND YOUNG ADULT CARDIAC CLINIC

When the adolescent or adult is evaluated, the office setting, staffing, ambience, and style of evaluation are different from the setting for newborns and toddlers. If treated in the same manner as used for young patients, this population will seek other resources. The clinic should be held separately from that for younger patients, and its setting should be geared toward the age of the patient population.

Depending on the patient's age and maturity, parents may or may not accompany the patient to the office visit. Some patients will come with their spouses and some will even bring their own children. Since many are young adults, unless the patient's development level prohibits understanding, the practitioner should deal with the patient privately as well as with those who accompany the patient. The adolescent and adult should understand that the cardiologist is willing to discuss certain issues in privacy and that these discussions are confidential. By this age, these patients should share in or primarily decide their courses of therapy and behaviors. "Weaning" the young adult from parental decision making is one of the real challenges facing patients as they reach adulthood.

Rather disturbing is the discovery that the same patient who was evaluated annually by a pediatric cardiologist saw a cardiologist only every 10 years after reaching the age of 21 (174). This indicates that a better and more accessible system must be provided to these patients. Because of lack of training and interest, some pediatric cardiologists, who are the best trained to understand most of the defects encountered in this population, do not care to be involved in the care of this age-group. Some internal medicine cardiologists have had minimal exposure to CHD during their training or experience

Figure 68.43. A: Chest radiograph of a 28-year-old patient with classic Fontan for tricuspid atresia with a severely enlarged cardiac silhouette mainly from the enlarged right atrium. B: Following Fontan revision the heart size is significantly decreased. Note epicardial pacing wires.

and are now expected to manage even the most complex of these patients. In fact, internal medicine cardiology training only requires 6 hours of CHD lectures to be board eligible for internal medicine cardiovascular boards (175).

The best present answer for adequate care of this population is a specialized ACHD clinic. Staffing adolescent and adult cardiac clinic varies from institution to institution. It usually includes a team of interested and experienced pediatric cardiologists, internal medicine cardiologists, cardiac surgeons experienced in dealing with congenital heart defects, nurse clinicians, and, occasionally, social workers. The milieu should include trainees from both pediatric and internal medicine disciplines so that a more coordinated effort can be secured for the future. The reality is that there are very few pediatric cardiologists compared with the number of internal medicine cardiologists, and that the transition of many of these patients to adult cardiologists is inevitable. Those providing care must be trained and have the ability to care for this unique population. More recently, internal medicine/pediatric-trained individuals are seeking specialized ACHD training and some have completed both internal medicine and pediatric cardiology training programs with the intent to care for this population.

Consultative access to obstetricians and gynecologists, psychiatrists, endocrinologists, nephrologists, hematologists, rheumatologists, pulmonologists, anesthesiologists, and pathologists, all with an understanding of CHDs and their impacts on this population, is most desirable (176).

Sources of general health care for the adolescent and adult can include pediatricians, most of whom discontinue care when the patient is 21 years old, internists, family practitioners, adolescent health specialists, athletic trainers, and student health center staff, including physicians and nurses. In many cases, the extent of their care may be no more than episodic emergency room visits. The physician trained in internal medicine–pediatrics residency may be the ideal primary care resource for these young people. When the patient has an identified primary provider, that person should be informed about, and frequently augment, recommendations that the clinic team offers to the patient.

In addition to assisting their parents through a sophisticated understanding of their heart problems, the practitioner in the ACHD clinic is expected to help the patient manage lifestyle issues. These include sexuality (including contraception, pregnancy, and evaluation of offspring), education and employability, insurability, and exercise and athletics (177,178).

The ongoing management of this complex patient population can often be challenging in the subset of patients with ACHD who have multiple physical and/or mental disabilities. It is not uncommon for adults with CHD to be living with their parents or to have complex psychosocial needs. Continuity of care may also be compromised by noncompliance in the presence of minimal or no symptoms or with the denial phase, which is common during adolescence. Finally, patients may be lost to follow-up when they move for education or work-related reasons (177,178).

The ACHD population is growing and for the foreseeable future will continue to grow. The estimated number of adults living with CHD is now greater than the estimated population of children with CHD. However, our resources, training, specialized care, research, and clinical trials in this field do not approach other subspecialty areas in cardiology. Although the prognosis for patients with CHD is improving, significant cardiovascular problems persist and limitations to long-term survival still exist. Recurrent vascular lesions, residual shunts, ventricular dysfunction, heart failure, PH, cyanosis, valvular disease, and SCD are unfortunate but realistic problems for the ACHD population. New research, specialized training and care, and legislative help are all necessary to improve the lives of those adults living with CHD.

Pregnancy in Young Women with Congenital Heart Disease

Candice K. Silversides ■ Jack M. Colman ■ Samuel C. Siu

In general, pregnancy is well tolerated in women with congenital heart disease. However, misconceptions are common. Discussions regarding contraception and pregnancy should begin once adolescent women reach an age when they may become sexually active. Optimal management includes a complete cardiac assessment prior to conception. This assessment should include a full review of the underlying cardiac lesion and prior surgical procedures, determination of the risk of pregnancy, and development of plans for cardiac interventions prior to pregnancy when indicated. Because the severity of a low-risk condition may be misinterpreted or given undue importance, even women with low-risk cardiac lesions often benefit from preconception counseling. All women need to understand which types of contraception are appropriate and safe. Unfortunately, among women with congenital heart disease preconception counseling is often not provided and knowledge of risks of contraception and pregnancy is often suboptimal (1–3).

Many issues need to be addressed in women with heart disease contemplating or undergoing pregnancy, including the risks for the mother and the baby, possible adverse effects of medication used during pregnancy, maternal long-term prognosis, and the risk of recurrence of cardiac disease in offspring (Table 69.1). The cardiologist plays a critical role by providing and/or ensuring informed education of the patient, her partner, and her caregivers.

PHYSIOLOGIC CHANGES DURING PREGNANCY

Maintenance of adequate oxygen delivery to maternal peripheral tissues as well as to the fetus is achieved through changes in maternal circulating blood volume, red cell mass, peripheral vascular compliance and resistance, heart rate, and cardiac output (Fig. 69.1) (4). These adaptive changes are usually well tolerated by women without heart disease; however, in some women with heart disease such changes result in cardiac decompensation. As well, preexisting heart disease may first be revealed during pregnancy when the heart is challenged by an increased hemodynamic burden.

Blood volume increases during pregnancy; the increase begins as early as the sixth week of gestation and peaks at an average of 50% more than the prepregnant state by the end of the second trimester (5,6) though individual increases range between 20% and 100% above prepregnant blood volume (7). Blood volume plateaus in the third trimester (8). Red cell mass increases during pregnancy to as much as 40% above prepregnancy levels (6,9). A “physiologic anemia of pregnancy” is seen because the increase in plasma volume is proportionately greater than the increase in red blood cell mass. In addition, there are increased levels of clotting factors and decreased fibrinolytic activity (10), both acting to promote the

hypercoagulability that underlies the increased risk for thromboembolism during pregnancy.

Systemic (peripheral) vascular resistance decreases beginning in the fifth week of gestation. This mediates a decrease in systemic arterial pressure that begins in the first trimester and reaches its nadir in midpregnancy, after which blood pressure stabilizes (11,12). After the 32nd week of gestation, the systemic vascular resistance slowly increases until term, accompanied by recovery of systemic arterial pressure, which ultimately reaches or exceeds prepregnancy levels. Placental blood flow increases until about the 25th week of gestation and then remains unchanged. Renal blood flow also increases, accompanied by a 50% increase in glomerular filtration rate (13). Increased blood flow to the hands and feet, nasal passages, and breasts results in warm erythematous extremities, nasal congestion, and breast engorgement, respectively. The impact of pregnancy on coronary blood flow has not been studied.

Cardiac output increases during pregnancy as a result of increases in both heart rate and stroke volume. Most of the early increase in cardiac output is a result of progressive increase in stroke volume, whereas later in pregnancy the heart rate effect becomes more important because the stroke volume stabilizes while the heart rate continues to rise (11,14). The mean heart rate increases to approximately 10 to 20 beats above prepregnancy levels by term. Increase in cardiac output begins as early as the fifth week of gestation, reaches its zenith near the end of the second trimester, typically after the 24th week of gestation and then plateaus till term at 30% to 50% above prepregnancy levels (11,15–17). Pregnant women with underlying cardiac disease have been shown to have lower cardiac output than pregnant women with normal cardiac function (18). Cardiac output can fall acutely if the inferior vena cava is compressed by the gravid uterus in the supine position, a phenomenon that can be reversed by assuming the left lateral decubitus position. Although increases in left ventricular ejection fraction during pregnancy have been reported by some, (11,16) other studies have not demonstrated this finding (17,19,20). Ejection fraction is sensitive to loading conditions, so the differences may be related to uncontrolled variation in preload or afterload among studies.

During labor and delivery pain, anxiety and uterine contractions result in tachycardia, hypertension, and further increases in cardiac output, sometimes provoking cardiac decompensation in women with heart disease. During labor, there is a 10% increase in cardiac output beyond the prelabor level, mediated by increases in heart rate and stroke volume, augmented by a further increase of 7% to 15% in response to each uterine contraction, with maximal augmentation noted during the second stage of labor (21). Immediately following delivery, cardiac output may transiently increase to as much as 80% above prelabor values due to relief of inferior vena cava compression and autotransfusion from the placenta, but

TABLE 69.1

Women of Childbearing Age with Cardiac Disease: Approach to Contraception and Pregnancy**Contraception**

- Patient education regarding contraception options

Preconception

- Preconceptual counseling should begin in adolescence
- All women with heart disease should receive preconception counseling including women with simple cardiac lesions in whom reassurance about the safety of pregnancy is an appropriate aspect of counseling
- Maternal cardiac risk of pregnancy should be assessed
- Long-term prognosis of the mother should be considered
- Fetal and neonatal risks during pregnancy should be assessed
- The safety of medication use during pregnancy should be determined
- The risk of transmission of congenital heart disease to offspring (including a formal clinical genetics assessment when appropriate) should be determined

Pregnancy

- For intermediate and high-risk patients, assessment by a multidisciplinary team including cardiologists and obstetricians knowledgeable in management of high-risk pregnancy should occur early in the pregnancy
- The patient should be advised of antepartum follow-up requirements
- Individualized antepartum management issues should be addressed
- Women with congenital heart disease or who are spouses of men with congenital heart disease should be offered fetal echocardiography
- Peripartum plans should be established and conveyed to all appropriate caregivers
- Intrapartum and postpartum management issues specific to each individual should be addressed

Figure 69.1. Hemodynamic changes during pregnancy. Changes in cardiac output (CO), stroke volume (SV), total peripheral vascular resistance (TPVR), heart rate (HR), and hemoglobin concentration (Hb) during pregnancy. (From Karamermer Y, Roos-Hesselink JW. Pregnancy and adult congenital heart disease. *Expert Rev Cardiovasc Ther* 2007;5:859–869, with permission.)

output returns to prelabor levels by approximately 1 hour postpartum. Thereafter, the hemodynamic changes that developed during pregnancy return toward baseline values; most of the changes resolve early after delivery, although complete resolution of all measureable pregnancy-associated effects may take as long as 6 months (22).

CARDIAC FINDINGS IN NORMAL PREGNANCY

Fatigue, dyspnea, light-headedness, and palpitations are normal symptoms associated with pregnancy but overlap with symptoms of cardiac decompensation. The hemodynamic changes of pregnancy are responsible for corresponding changes in the physical examination that can mimic cardiac disease. They include displacement of the apical impulse, prominence of the jugular venous pulsation, wide splitting of the first and second heart sounds, soft systolic flow murmurs, and continuous murmurs. Sinus tachycardia and premature atrial or ventricular ectopic beats may also increase in frequency during normal pregnancy and do not necessarily reflect cardiac decompensation or any cardiac disease. This overlap of signs and symptoms may make diagnosis of cardiac decompensation during pregnancy challenging; brain natriuretic peptide can be a useful test to adjudicate the basis for symptoms and signs when a benign basis is not certain (23).

On the 12-lead electrocardiogram during normal pregnancy, there may be a leftward shift in the frontal axis, T-wave inversion in lead II, and ST-segment depression. Echocardiographic studies during normal pregnancy show that dimensions of all four cardiac chambers increase and there is an increase in left ventricular wall thickness and mass (16,22,24,25). Increases in transvalvular flow velocities are seen (26). Mitral, tricuspid, and pulmonic annular diameters increase and may result in increasing degrees of mitral, tricuspid, and pulmonic regurgitation, respectively (27).

ASSESSMENT OF PREGNANCY RISK IN WOMEN WITH CONGENITAL HEART DISEASE: GENERAL CONCEPTS AND GLOBAL EVALUATION

Women with cardiac disease are at increased risk of developing adverse maternal cardiac events during pregnancy (28). Maternal cardiac risk can usually be predicted after a complete cardiovascular history and physical examination, a 12-lead electrocardiogram, a transthoracic echocardiogram, and arterial oxygen saturation when indicated. Echocardiography is safe during pregnancy. Prepregnancy exercise testing, specifically focusing on measures of heart rate responsiveness to exercise, may aid risk stratification (29).

Early studies showed that poor maternal functional class and cyanosis are associated with adverse maternal cardiac events (30,31). Subsequently, a prospective multicenter study addressed global risk assessment of pregnant women with congenital and acquired heart disease and identified poor functional status (NYHA > II) or cyanosis, systemic (subaortic, "left") ventricular systolic dysfunction, left heart obstruction, and history of cardiac events prior to pregnancy (arrhythmia, stroke, or pulmonary edema) as independent predictors of maternal cardiac events during pregnancy. Based on these predictors, women can be classified into low (0 predictor), intermediate (1 predictor), or high (>1 predictor) risk categories. The study showed that women in low, intermediate, and high-risk categories have, respectively, a 5%, 25%, or >75% chance of

developing an adverse cardiac event during pregnancy (Table 69.2) (Fig. 69.2) (32). This risk score, sometimes referred to as the CARPREG score, has been validated by other groups (33). Additional risk predictors have also been suggested. A single-center retrospective study that validated the CARPREG index in a population limited to congenital heart disease reported also that subpulmonary ventricular dysfunction and/or severe pulmonic regurgitation were additional independent risk factors for adverse maternal outcomes (33). The ZAHARA investigators carried out a large multicenter retrospective review of outcomes in pregnant women, also limited to congenital heart disease ($n = 1,302$ pregnancies in 714 women) and derived a more complex weighted risk score that included additional factors such as mechanical valve replacement and moderate or severe subaortic (systemic) or subpulmonary atrioventricular valve regurgitation (34).

Any global risk index should be used in conjunction with lesion-specific risk estimates, since certain intermediate or high-risk lesions may not have been represented in the population from which the global risk index was derived. For example, women with Marfan syndrome and dilated aortic roots, with Eisenmenger syndrome, or with a Fontan circulation were underrepresented in the derivation sets. Therefore, their known pregnancy-associated risks will not be reliably predicted by the global risk scores. Figure 69.3 shows pooled estimates of maternal and fetal and/or neonatal risks in women with congenital heart disease, stratified by lesion, derived primarily from retrospective single-center studies. Additional described factors that increase pregnancy risk include the presence of a prosthetic valve or conduit (especially if associated with abnormal prosthetic valve function), occurrence of an obstetric complication such as preeclampsia, and use of anticoagulants or teratogenic drugs. Some of these matters are elaborated further in sections that follow. In comprehensive assessment of maternal risk, it is helpful to integrate a global risk index with contemporary lesion-specific and other markers of risk. When there is discordance between the global and the lesion-specific estimates of risk, the higher-risk estimate should drive the care plan to avoid false reassurance.

In addition to increased risk of adverse maternal cardiac events, women with cardiac disease are at increased risk for adverse fetal and neonatal complications, which include fetal or neonatal death, premature birth and its associated complications (respiratory distress syndrome, intraventricular hemorrhage), or small-for-gestational-age birth weight neonates (28,35) (Fig. 69.4). Maternal cardiac risk factors for adverse fetal and neonatal outcomes have been identified (Table 69.2) (32). The risk of neonatal complications is further increased if there are concomitant maternal noncardiac (obstetrical and other) risk factors (Table 69.2) (Fig. 69.5). Finally, there is cardiac-lesion-specific variation in the risk for adverse obstetric outcomes during pregnancy (Fig. 69.3) (35).

Women with an intermediate to high risk of adverse maternal cardiac events during pregnancy or those at increased risk for fetal and neonatal complications should be considered for enhanced multidisciplinary surveillance in specialized high-risk cardiac and obstetric programs where these are available. As well, the impact of maternal heart disease on the probability of adverse obstetric outcomes should be considered when evaluating the need for enhanced intensity of obstetric oversight of pregnancy.

Hemodynamic and hormonal changes of pregnancy may continue to impact maternal outcomes late after pregnancy (36–40). For example, adverse cardiac events late after pregnancy occurred more often in women who had had adverse cardiac events during pregnancy (38) (Fig. 69.6). At this time, the full extent and mechanisms of the late effects of pregnancy on the heart are poorly understood.

TABLE 69.2

Risk Factors for Adverse Maternal Cardiac and Fetal/Neonatal Events During Pregnancy in Women with Heart Disease

Adverse Event	Risk Factor
Maternal cardiac adverse event ^a	■ Poor functional class (NYHA Class III or IV) or cyanosis
	■ Systemic ventricular ejection fraction <40%
	■ Left heart obstruction (mitral valve area <2 cm ² , aortic valve area <1.5 cm ² , or peak left ventricular outflow tract gradient >30 mm Hg)
	■ Cardiac event (sustained or symptomatic arrhythmias requiring treatment, stroke, pulmonary edema) prior to pregnancy
	■ Subpulmonic ventricular dysfunction
	■ Significant pulmonary regurgitation
	■ Mechanical heart valves
	■ Moderate or severe subaortic or subpulmonary atrioventricular valve regurgitation
	■ Known lesion-specific risk
Fetal and/or neonatal adverse event ^b	■ Poor maternal functional class (NYHA Class III or IV) or cyanosis
	■ Maternal left heart obstruction (defined above)
	■ Maternal age <20 or >35 years
	■ Obstetric risk factors ^c
	■ Multiple gestation
	■ Smoking during pregnancy
	■ Anticoagulant therapy
	■ Known lesion-specific risk

The risk factors highlighted in red are components of the CARPREG risk index: the risk of a maternal cardiac adverse event with zero risk factors present is <5%, with one risk factor present is 25%, and with more than one risk factor present is 75% (32).

Additional risk factors identified from subsequent studies on pregnancy risk (33,34).

^aMaternal cardiac adverse events include pulmonary edema, arrhythmia, stroke, or death.

^bFetal/neonatal adverse events include premature birth, small-for-gestational age birth weight, respiratory distress syndrome, intraventricular hemorrhage, or fetal or neonatal death.

^cHistory of premature delivery or rupture of membranes, incompetent cervix, or caesarean section; or intrauterine growth retardation, antepartum bleeding >12 weeks gestation, febrile illness, or uterine/placental abnormalities during present pregnancy.

Cardiac Event Rate (% Pregnancies)

Figure 69.2. Frequency of adverse maternal cardiac events in pregnancy as predicted by the CARPREG risk index. Frequency of primary maternal cardiac events, as predicted by the CARPREG risk index (32), and observed in derivation and validation groups, expressed as a function of the number of predictors (x axis). (From Siu SC, Sermer M, Colman JM, et al. Prospective multicenter study of pregnancy outcomes in women with heart disease. *Circulation* 2001;104:515–521, with permission.)

LESION-SPECIFIC RISKS AND OUTCOMES

Pooled estimates of the frequency of adverse pregnancy outcomes (maternal cardiac, fetal, neonatal, and obstetric), stratified according to type of congenital heart disease, are presented in Figure 69.3 (35). Pregnancy outcomes stratified solely by diagnosis can be helpful, but in addition, it is important to consider the specific surgical history, the history of prior cardiac events, the functional status of the woman, and ventricular and valve function, since individual variation in these factors may influence risk over and above the risk imparted by diagnosis alone.

Cardiac shunts. Women with uncorrected left-to-right shunts, including secundum atrial septal defect (ASD), ventricular septal defect (VSD), and patent ductus arteriosus (PDA) are at low risk for adverse maternal cardiac events during pregnancy, in part because the pregnancy-associated fall in peripheral vascular resistance mitigates the effect of volume overload on the ventricle (30,32,41–44). Potential complications include atrial arrhythmias and heart failure, particularly if the shunt is large. In women with ASD or patent foramen ovale, there is a potential for paradoxical embolization if systemic vasodilation and/or elevation of pulmonary resistance

result in transient right-to-left shunting. Atrioventricular septal defects (AVSDs) are more complex, and pregnancy may be less well tolerated. In one study of 62 pregnancies (29 women) in women with AVSD, cardiac complications including persistent NYHA functional class deterioration, arrhythmias, and heart failure were reported to be 23%, 19%, and 2%, respectively (45). If cardiac shunts are associated with pulmonary hypertension, risk is dominated by the impact of the elevated pulmonary vascular resistance, which is discussed elsewhere in this chapter.

Right ventricular outflow tract obstruction. If pulmonic stenosis is mild or has been previously corrected surgically or by valvuloplasty, it is typically well tolerated during pregnancy (32,41,46). In severe pulmonic stenosis, the increase in preload associated with pregnancy may not be tolerated and may result in atrial arrhythmias or right heart failure. Thus, correction of severe pulmonic stenosis prior to pregnancy should be considered. If decompensation develops during pregnancy, balloon valvuloplasty can be carried out if initial medical therapy proves insufficient (47). Although one group

Figure 69.3. Estimates of maternal cardiac, fetal and neonatal, and obstetric outcomes during pregnancy in women with congenital heart disease. AOS, aortic stenosis; ASD, atrial septal defect; AVSD, atrioventricular septal defect; ccTGA, congenitally corrected transposition of the great arteries; CoA, aortic coarctation; Ebstein, Ebstein anomaly; Eisenmenger, Eisenmenger syndrome; Fontan, patients after Fontan repair; PAVSD, pulmonary atresia with ventricular septal defects; PS, pulmonary valve stenosis; TGA, complete transposition of the great arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect; TEC, thromboembolic complication; SGA, small for gestational age. (From Drenthen W, Pieper PG, Roos-Hesselink JW, et al. Outcome of pregnancy in women with congenital heart disease: a literature review. *J Am Coll Cardiol* 2007;49:2303–2311, with permission.)

Figure 69.3. (Continued)

has reported high rates of obstetric and fetal complications in women with pulmonary stenosis (48), this differs from experience reported elsewhere (32,41,46).

Tetralogy of Fallot. Most women with tetralogy of Fallot would have undergone surgical correction with closure of the VSD and relief of right ventricular outflow tract obstruction. After repair, women may be left with residual shunts, right ventricular outflow tract obstruction, pulmonary regurgitation, right ventricular dilation or dysfunction, and atrial or ventricular arrhythmias. In general, pregnancy is well tolerated, but risk of complications is increased in presence of such residual and surgical sequelae. In one series, maternal complications

including symptomatic right heart failure, arrhythmias, or both occurred in 12% of pregnancies (49), though other studies have reported lower adverse event rates (50–52). Adverse maternal cardiac events have been reported in association with maternal cardiac factors (left ventricular dysfunction, severe pulmonary hypertension, severe pulmonic regurgitation with right ventricular dysfunction, or right ventricular outflow tract obstruction) and obstetric risk factors (twin pregnancies) (50,51).

Following biventricular repair for double outlet right ventricle a low risk for adverse maternal cardiac complications was reported in one series; however, the risk of fetal, neonatal, and obstetric complications was increased (53).

Event rate (% pregnancies)

Figure 69.4. Rate of fetal and/or neonatal adverse events in 302 consecutive women with heart disease and 572 controls. Event rates in heart disease (black bars) and controls (white bars) subdivided into specific type of neonatal complication. Prem birth indicated birth at <37 weeks gestation; SGA small-for-gestational-age birth weight; RDS or IVH respiratory distress syndrome or intraventricular hemorrhage; and death, fetal, or neonatal death. (From Siu SC, Colman JM, Sorensen S, et al. Adverse neonatal and cardiac outcomes are more common in pregnant women with cardiac disease. *Circulation* 2002;105:2179–2184, with permission.)

Neonatal event rate (% pregnancies)

Figure 69.5. Frequency of fetal and/or neonatal complications according to presence and risk profile of cardiac lesion and the presence of maternal high-risk obstetric characteristics. High-risk obstetric characteristics include smoking, use of anticoagulation, multiple gestations, and maternal age. Control group is represented by empty bars. Heart disease group with neither left heart obstruction nor poor functional class/cyanosis is represented by grey bars. Heart disease group with left heart obstruction or poor functional class/cyanosis is represented by black bars. (From Siu SC, Colman JM, Sorensen S, et al. Adverse neonatal and cardiac outcomes are more common in pregnant women with cardiac disease. *Circulation* 2002;105:2179–2184, with permission.)

Figure 69.6. Incidence of adverse cardiac events late after pregnancy according to the presence or absence of pregnancy-related adverse cardiac events. Time 0 = date of delivery. (From Balint OH, Siu SC, Mason J, et al. Cardiac outcomes after pregnancy in women with congenital heart disease. *Heart* 2010;96:1656–1661, with permission.)

Left ventricular outflow tract obstruction. Significant left ventricular outflow tract obstruction most commonly occurs as a result of aortic stenosis due to bicuspid aortic valve disease and limits the ability of the heart to increase cardiac output. Abnormal elevation of left ventricular filling pressures may also occur. The hypertrophied, noncompliant ventricle is more sensitive to a fall in preload. During pregnancy, all of these factors contribute to an increased propensity to heart failure, ischemia, or hypotension. Bicuspid aortic disease is commonly associated with ascending aortopathy and sometimes with coarctation of the aorta, which confer additional risks during pregnancy. Maternal mortality is not as high as once described (54,35). However, women with significant aortic stenosis continue to be at risk for heart failure, arrhythmias, and angina (46,54–56). We recently reported that assessment of ventricular torsion, a novel echocardiographic parameter, may provide additional insights into why some women with aortic stenosis deteriorate during pregnancy and has the potential to be an additional risk stratifier (57). Women with symptomatic aortic stenosis should undergo correction prior to pregnancy (58). Asymptomatic women with mild to moderate aortic stenosis typically do well. Management of asymptomatic women with severe aortic stenosis is more controversial and careful risk stratification prior to pregnancy is required. In select women, aortic valvuloplasty may provide short-term palliation prior to a planned pregnancy. In general, we do not advocate prophylactic surgery in women with severe asymptomatic aortic stenosis who otherwise would not be candidates for valve surgery if pregnancy were not a consideration. Palliation by balloon valvuloplasty can be accomplished during pregnancy if necessary and when anatomy allows (59). Pregnancy may increase the risk of cardiac events late after pregnancy; for example, women with aortic stenosis who had had a pregnancy were more likely to require aortic valve replacement than a matched control group of women who had not been pregnant (40,55).

Aortic dissection has been reported in women with bicuspid aortic valve and aortopathy although overall risk is likely lower than in women with aortopathy associated with Marfan syndrome (60). The approach to the aortopathy associated with bicuspid aortic valve at our center is to offer empiric beta-blockade and serial echocardiographic assessment during pregnancy.

Coarctation of the aorta. In the current era, most women with coarctation of the aorta would have undergone repair

prior to pregnancy. Even when there is no residual coarctation, persistent or recurrent systemic hypertension may manifest after repair. Significant coarctation of the aorta impedes delivery of blood to the arterial tree distal to the coarctation site; during pregnancy this may impact on the placental circulation. Upper body hypertension and concomitant aortic valve disease pose additional risks. Maternal mortality has been reported, but this is rare in contemporary series (61,62). Women with Turner syndrome are at higher risk such that most experts advise against pregnancy in the presence of aortopathy of any sort (63), and some recommend against pregnancy even with a normal aorta, though it may be technically feasible with the assistance of reproductive technology, and occasionally spontaneously. Women with repaired coarctation are at increased risk for pregnancy-induced hypertension and preeclampsia (32,41,64). The risk of hypertension is highest in women with unrepaired coarctation in proportion to the degree of residual gradient (61,62). Miscarriages are common (62). Control of upper body hypertension during pregnancy may result in hypotension distal to the coarctation site with potential adverse impact on oxygen delivery to the fetus. Intrauterine growth restriction and premature labor are more common in women with unrepaired coarctation.

Marfan syndrome. In Marfan syndrome, increased cardiac output, hypervolemia, and the hormonal milieu of pregnancy contribute to increased risk of aortic dilation and dissection. Women with smaller aortic root dimensions are at lower risk for aortic complications than those with dilated aortic roots (>40 mm) or prior aortic root surgery (65,66). Favorable pregnancy outcomes were reported in a series of 33 women with aortic root size <45 mm prior to pregnancy (36). On the other hand, a European consensus document estimates that 1% of women with aortic diameters <40 mm and no significant aortic or mitral regurgitation will develop dissection or other serious maternal cardiac complication and that 10% of women with an aortic diameter more than 40 mm will develop dissection (67). Unfortunately, prophylactic root replacement prior to pregnancy or the presence of a normal-sized aortic root does not guarantee a safe pregnancy as it is possible for dissection to occur in an aorta that appears “normal” by imaging or in the segment distal to a prior repair (66). Patients with significant aortic root dilation should receive preconception counseling. If seen first only in early pregnancy they should be offered termination. For women with Marfan syndrome whose aortic

size is normal, counseling should incorporate discussion of the increasing risk with increasing maternal age, and explain that if pregnancy is contemplated it is best achieved at a younger age. Women with Marfan syndrome have a 50% chance of transmitting the syndrome to offspring. In addition, they are at increased risk for fetal, neonatal, and obstetric complications, the most common of which is preterm delivery due to premature rupture of membranes and cervical incompetence (68). Fetal and neonatal mortality of 7% has been reported (68).

Ebstein anomaly. There is substantial variability in the clinical phenotype of Ebstein anomaly, and the ability of the heart to tolerate a pregnancy varies according to the severity of the disease. Women with milder anatomic variations who are acyanotic can expect to have an uncomplicated pregnancy, whereas women with severe Ebstein anomaly may be unable to tolerate the increased preload and cardiac output of pregnancy and as a consequence are at risk for functional deterioration, right heart failure, and arrhythmia (69). In the largest published pregnancy series, no serious maternal cardiac complications (maternal death, congestive heart failure, arrhythmias, stroke) were reported; however, there was an increased risk of fetal loss, prematurity, and congenital heart disease in the offspring (70). Women with interatrial shunts may demonstrate reversal to or increase in right-to-left shunting, hence increasing cyanosis during pregnancy, and are at high risk for complications as a consequence.

Transposition of the great arteries. Women with complete transposition of the great arteries would have undergone an atrial switch operation (Mustard or Senning procedure), an arterial switch operation (Jatene procedure), or, less commonly, a Rastelli repair. Late complications after atrial switch operations include sinus node dysfunction, atrial arrhythmias, systemic ventricular dysfunction, and systemic atrioventricular valve regurgitation, all of which may contribute to complications during pregnancy, including, rarely, maternal death (32,71–73). Arrhythmias are the most common cardiac complication during pregnancy. In the largest published series they occurred in 22% of pregnancies (73), more commonly in women with a history of prior arrhythmias. The same series reported a high incidence of obstetric complications and mortality in the offspring (73). Other complications seen during pregnancy include heart failure and deterioration in cardiac function (71,72). Pregnancy has been associated with progressive subaortic right ventricular dilation (31%) and deterioration in subaortic right ventricular function (25%) determined by qualitative echocardiographic assessment (37).

Women treated with the Jatene operation are now reaching childbearing age, but reported experience during pregnancy is limited. Successful pregnancy outcomes have been described; however, complications including valve thrombosis in a woman with a mechanical valve and ventricular arrhythmia have been reported (74,75).

Congenitally corrected transposition of the great arteries can be associated with systemic ventricular dysfunction and systemic atrioventricular valve regurgitation. Associated lesions are common, especially VSD, pulmonary stenosis, or complete heart block. Potential problems in pregnancy include heart failure as a result of a dysfunctional subaortic (systemic) right ventricle and/or increased subaortic (tricuspid) atrioventricular valve regurgitation, atrial arrhythmias, atrioventricular block, and late sequelae from prior surgical interventions (e.g., dysfunction of a right ventricular to pulmonary artery conduit). In the two largest published series, no maternal mortality was reported; (76,77) however, approximately 25% of women developed adverse cardiac events during pregnancy including heart failure, endocarditis, stroke, or myocardial infarction (77).

Fontan circulation. The Fontan operation for functionally single ventricle palliates the condition by directing right atrial

or caval blood into the pulmonary artery, generally with no subpulmonary ventricle in the circuit. Although the operation improves cyanosis and volume overload of the subaortic (systemic) ventricle, the ability of the heart to increased cardiac output is limited. In addition, scarring and remodeling of the atria contribute to atrial arrhythmias and atrial thrombi. The largest series of pregnancies in a selected group of high-functioning women after Fontan operation reported good maternal outcomes with no maternal mortality (78). Supraventricular tachycardia, atrial fibrillation, and deterioration of NYHA functional class did occur (78,79). The reasonably good reported maternal cardiac outcomes were likely the result of preconceptual counseling and careful patient selection, as most or all the patients reported had a favorable clinical profile. Fetal and neonatal adverse outcomes remain common with only 45% of pregnancies resulting in live births in one series (78). The incidence of first trimester miscarriage is high.

Cyanotic heart disease. Women with cyanotic congenital heart disease are at substantial risk for pregnancy-associated adverse events, in proportion to the degree of maternal hypoxemia and cyanosis. In the largest series ($n = 96$ pregnancies) adverse maternal cardiac events occurred in 32% of pregnancies and included one death from endocarditis after delivery. Other adverse cardiac events included heart failure, arrhythmias, pulmonary artery thrombosis, and cerebral infarction. Prematurity was common, occurring in 37% of pregnancies. There was a low live birth rate, 43% overall; if the maternal oxygen saturation was $\leq 85\%$, the live birth rate was only 12% (80).

In women with Eisenmenger syndrome, pregnancy-associated decrease in afterload facilitates increase in right-to-left intracardiac shunting, leading to increasing hypoxemia and cyanosis. There is a high maternal mortality ($\sim 30\%$ per pregnancy) (81–83). Women with Eisenmenger syndrome are particularly sensitive to the volume depletion and hypotension that can occur during labor and delivery. Deaths are most likely to occur within the first few weeks postpartum. Preconceptual counseling should advise against pregnancy. Termination of pregnancy should be offered to such patients if counseled early in pregnancy. High maternal mortality during pregnancy is reported in women with pulmonary hypertension from other causes and recommendations regarding preconceptual counseling and pregnancy termination are similar to those for Eisenmenger syndrome. In the event that pregnancy continues, the use of pulmonary vasodilators is being increasingly reported and may be beneficial in reducing pulmonary artery pressures (83,84). One series of 11 pregnancies in women with pulmonary hypertension managed by an experienced team and treated with pulmonary vasodilators reported no maternal deaths (84). Adverse fetal events are common. Perinatal mortality, most of which was associated with prematurity, has been reported at 28% (81).

Prosthetic heart valves. Risks of complications during pregnancy in women with prosthetic valves are dependent on the type of valve and its position, the baseline function of the prosthesis, and the type of anticoagulant used. Women with normally functioning bioprosthetic valves often tolerate pregnancy well. Although there had been concern that degeneration of bioprosthetic or homograft valves may be accelerated by pregnancy, this has not been confirmed in all studies (85–87). Women with pulmonary autograft aortic valve replacement (Ross procedure) are reported to do well during pregnancy (88,89). Although mechanical valves have excellent durability, women with mechanical valve prostheses are at increased risk for thromboembolic events, primarily valve thrombosis, which is seen in 4% to 9% of pregnancies depending on the study and the anticoagulant regime, and maternal bleeding secondary to anticoagulation, seen in 2.5% of pregnancies (58,90,91). Warfarin embryopathy has been reported to be

less frequent in pregnant women who can be therapeutically controlled on ≤ 5 mg of warfarin per day (92,93).

TRANSMISSION OF CARDIAC DISEASE TO OFFSPRING

The risk of recurrence of congenital heart disease in offspring should be discussed prior to pregnancy when opportunity exists. Estimating recurrence risk is complex and should factor in the type of cardiac defect of the parent(s), other patient characteristics, and the presence of congenital heart disease in other family members (94). Formal clinical genetic counseling is often helpful and should be offered. In patients with congenital heart disease who do not have specific genetic syndromes, the recurrence risk of congenital heart disease to offspring is approximately 3% to 5% (95,96). Some studies have suggested higher rates of transmission if the affected parent is the mother rather than the father (96,97), though others have found no such difference (98). Parental left heart obstructive lesions are associated with higher rates of transmission (13% to 18%) (96). Autosomal dominant conditions such as Noonan syndrome (99), Williams syndrome (100), Holt-Oram syndrome (101), Marfan syndrome, or 22q11.2 deletion syndrome confer a 50% risk of recurrence in an offspring. The presence of congenital heart disease in a family member of the mother or father should raise the possibility of a familial or autosomal dominant form of inheritance. Preconception use of multivitamins containing folic acid has been shown to decrease the incidence of congenital defects and should be encouraged (102). A fetal echocardiogram is indicated when a parent has congenital heart disease to assess the fetus for congenital cardiac anomalies. After delivery, pediatric cardiac assessment should be offered as it has incremental diagnostic utility for detection of congenital heart disease in the offspring of women with congenital heart disease (103).

MANAGEMENT ISSUES DURING PREGNANCY

Risk assessment and management of pregnant women with congenital cardiac disease is addressed to some extent in comprehensive adult congenital heart disease guidelines from the American Heart Association/American College of Cardiology (104), the Canadian Cardiovascular Society (105–109), and the European Society of Cardiology (110). The European Society of Cardiology also published a specific expert consensus document on management of cardiovascular diseases during pregnancy in 2003 (67).

Preconception Issues

Preconceptual counseling should be offered to all women with cardiac disease contemplating pregnancy. Counseling should include assessment of the maternal risk of pregnancy and the effects of the maternal cardiac condition on fetal outcomes. The risks and benefits of drug therapy need to take into account the health and safety of the mother and of the fetus. Exposure to teratogens such as alcohol, hydantoin, lithium, retinoic acid, valproic acid, and warfarin is associated with cardiovascular defects in offspring; therefore, use of such agents should be terminated prior to conception if possible. Drug dosing and frequency of administration of continued medication may need adjustment in pregnancy because of changes in volume of distribution, glomerular filtration rate, and hepatic metabolism.

In circumstances where maternal life expectancy may be limited, the issue of long-term prognosis should be addressed to allow women and their families to make informed decisions regarding pregnancy. Such a discussion should also include consideration of possible effects of pregnancy on progression of maternal heart disease and of need for earlier cardiac intervention. However, uncertainties regarding the effect of pregnancy on late maternal prognosis need to be acknowledged, as very little data are available in this regard (37,40).

Antepartum Issues

Women with heart disease who are at low risk for complications can typically be managed in local obstetric units. Conversely, women who are at intermediate or high risk for complications should receive care in a high-risk obstetrics unit from a multidisciplinary team including obstetricians, cardiologists, anesthesiologists, pediatricians, and others as indicated. Regardless of the perceived risk level, all pregnant women with heart disease not previously evaluated should be offered a consultation with an experienced cardiologist and obstetrician, ideally in an interdisciplinary program where maternal cardiac, obstetrical, and fetal issues can be addressed by appropriate specialists.

The optimal frequency of cardiac follow-up during pregnancy in women with heart disease needs to be individualized. In general, an early assessment (first trimester) is useful to establish the baseline and to initiate planning. Peak cardiac output occurs near the end of the second trimester so assessment at this time allows for cardiac evaluation at a point at which maximal hemodynamic stress is evident. A third trimester visit around the end of the eighth month ensures that the patient is stable prior to delivery. Women who are symptomatic and those at higher risk need to be seen more frequently.

Echocardiography is the cardiac imaging modality of choice during pregnancy. We perform transthoracic echocardiography during the baseline antenatal visit as part of risk stratification. We will often repeat the echocardiographic examination at the time of the late second-trimester assessment particularly in patients who are at risk of deterioration as a result of the hemodynamic burden associated with advancing pregnancy. Cardiac magnetic resonance imaging (MRI) can be used during pregnancy when necessary. If possible, MRI should be performed after the first trimester because the effect of MRI on early fetal development has not been well studied. Gadolinium, the commonly used MRI contrast agent, crosses the placenta and is contraindicated during pregnancy. Potential fetal risks of MRI include the effects of heat, noise, and the magnetic field on the developing fetus (111). Ionizing radiation (computed tomography, cardiac catheterization, nuclear imaging) should be avoided during pregnancy unless there are no alternatives. However, when clearly indicated, x-ray procedures such as coronary arteriography should not be withheld. Modification of technique (e.g., radial artery approach for coronary arteriography, abdominal shielding) can minimize fetal radiation exposure (112).

Ambulatory ECG monitoring is often useful in women with symptomatic palpitations to diagnosis arrhythmia, determine arrhythmia burden and monitor the effect of therapy. Because benign palpitations are common, symptom–rhythm correlation provided by ambulatory monitoring may relieve unnecessary concern and may avoid inappropriate therapy.

Management of Heart Failure

Women with limited cardiac reserve are at risk of developing heart failure as a consequence of the increased hemodynamic burden of pregnancy. Other causes of deterioration of

cardiac status such as gestational hypertension, hyperthyroidism, and anemia should be considered as well. In women with symptomatic heart failure, activity limitation may be helpful. Acute heart failure should be treated with oxygen, diuretics, and afterload-reducing agents such as hydralazine. Nitroprusside may be toxic to the fetus and should be avoided. For women with preexisting systemic ventricular dysfunction, beta-blockers can be used in pregnancy, but women need to be informed of potential fetal and neonatal risks. Digoxin is safe in pregnancy. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are associated with birth defects and should be avoided (113,114).

Management of Arrhythmias

The hemodynamic and hormonal changes of pregnancy may provoke or exacerbate arrhythmias. Women with a history of arrhythmias are at increased risk for adverse maternal cardiac events during pregnancy, including arrhythmia recurrences (41). Recurrence of arrhythmias during pregnancy is associated with an increase in adverse fetal and neonatal events (115). However, pharmacologic therapies may have undesirable effects on the developing fetus or neonate and so should be reserved for patients with significant symptoms or when sustained episodes result in hemodynamic compromise or intolerable symptomatology. Hemodynamically significant arrhythmias should be treated promptly, but teratogenic drugs should be avoided when possible.

In women with paroxysmal supraventricular tachycardia, including atrioventricular nodal reentrant tachycardia and atrioventricular reentrant tachycardia, beta-blockers can be used for arrhythmia prophylaxis. The treatment of an acute exacerbation of tachycardia in the pregnant woman is generally similar to that in the nonpregnant patient. Intravenous adenosine or beta-blockers can be used for acute management of supraventricular arrhythmias (116,117). Amiodarone is a FDA class D drug and is relatively contraindicated because it may impair neonatal thyroid function (118,119). Cardioversion is considered safe, although there is a theoretical risk of inducing fetal tachyarrhythmias (117).

There are many causes of ventricular tachycardia. During pregnancy, prophylactic therapy for ventricular tachycardia should be tailored according to the underlying condition. For instance, women with catecholamine-sensitive ventricular tachycardia are best treated with beta-blockers. Women with ventricular tachycardia in the setting of congenital heart disease will likely require antiarrhythmic therapy, but choice of medication needs to be individualized. Intravenous procainamide, sotalol, amiodarone, or beta-blocker can be used for acute management (120).

Bradyarrhythmias are less common during pregnancy. Pacemakers and implantable cardioverter-defibrillators are safe during pregnancy (121). Management of arrhythmias during pregnancy and safety profiles of antiarrhythmic medications can be found elsewhere (122).

Management of Anticoagulation

Pregnancy is associated with changes in clotting factors and fibrinolysis that increase the risk of thrombosis and thromboembolism. Consequently, optimized anticoagulation therapy is of utmost importance, especially for women with mechanical heart valves. The specific type of anticoagulant used during pregnancy must be carefully individualized. Options include warfarin, unfractionated heparin, low-molecular-weight heparin (LMWH), and adjunctive aspirin. Risks and benefits of various anticoagulant regimens should be discussed with the patient. High-risk women, such as those with early generation

mechanical heart valves (e.g., Starr-Edwards and Bjork-Shiley valves), have a greater risk of thromboembolic events, and consequently, anticoagulant regimens need to be more aggressive (123,124). In a systematic review of studies examining anticoagulation regimens and pregnancy outcomes in women with prosthetic heart valves, the pooled maternal mortality was 2.9% (91). The use of oral vitamin K antagonists (e.g., warfarin) throughout pregnancy was associated with the lowest rate of thrombosis, 3.9%. The substitution of unfractionated heparin between week 6 and week 12 gestational age only was associated with a 9.2% risk of valve thrombosis, whereas the use of unfractionated heparin throughout pregnancy carried a much higher 33.3% risk of valve thrombosis. The main concern regarding use of warfarin is its potential for embryopathy; however, there is evidence that a daily warfarin dose of ≤ 5 mg (assuming therapeutic anticoagulation can be achieved with such a dose) may not be teratogenic (92). When the mother takes warfarin, fetal intracranial bleeding is a risk throughout pregnancy and particularly during vaginal delivery. Thus warfarin should be replaced by heparin at least 2 weeks prior to labor (58). Adjusted-dose subcutaneous unfractionated heparin does not cross the placenta and has no teratogenic effects, but maintenance of therapeutic anticoagulation is difficult. Use of heparin may result in maternal thrombocytopenia and osteoporosis. LMWH is easier to administer and appears to be a satisfactory, though not risk-free, alternative to adjusted-dose unfractionated heparin (125–128).

Guidelines for the use of anticoagulants during pregnancy in women with mechanical valves have been offered by the American Heart Association/American College of Cardiology (129), the American College of Chest Physicians (124), and the European Society of Cardiology (130). Differences exist among the guidelines. For instance, the American College of Chest Physicians guideline includes as a treatment option the use of LMWH throughout pregnancy whereas the European Society of Cardiology guidelines do not recommend LMWH. Some experts suggest an alternative approach based on a modification of the guidelines to include further stratification based on risk of thrombosis (123). However, all current recommendations are based on case series and expert opinion as there are no data available from randomized trials. Our current approach includes offering women with mechanical valves LMWH as an alternative anticoagulation strategy to continued use of warfarin. For women at high thromboembolic risk (those with older style valves, more than one mechanical valve, prior thromboembolic events), we suggest adjunctive aspirin. Anticoagulation in pregnancy is often best managed in a specialized thrombosis clinic. At our center, all women are seen by a hematologist associated with the thrombosis clinic, are counseled in regard to the advantages and risks associated with various regimens, and are asked to sign a written consent acknowledging that they are aware of the issues and agree to the treatment chosen. It is clear that no specific strategy can fully mitigate the risk of pregnancy for women who require anticoagulation, particularly those with mechanical valves.

High-Risk Conditions

Women with cyanotic cardiac lesions (30) or symptomatic obstructive lesions (58) should be referred for repair prior to conception when possible. If a woman with Eisenmenger syndrome does not accept advice to terminate, or presents late in pregnancy, early hospitalization may be required along with supplemental oxygen and possibly empiric anticoagulation. Pulmonary vasodilators have been used in pregnant women with pulmonary hypertension including those with Eisenmenger

syndrome (83,84). However, some commonly used pulmonary vasodilators such as the endothelin receptor blockers cannot be used during pregnancy because of teratogenicity.

The risk in Marfan syndrome increases in proportion to aortic root size and is very high when aorta is already enlarged prior to pregnancy. Surveillance during pregnancy should include echocardiograms approximately every 6 weeks up to 6 months postpartum to monitor the size of the aortic root. Prophylactic beta-blockade is indicated in patients with Marfan syndrome. We recommend continuation of such therapy throughout pregnancy and thereafter. In patients not previously so treated we do recommend at our initial encounter that beta-blocker be started and continued (131).

Cardiac Surgery During Pregnancy

Cardiovascular surgery during pregnancy is associated with significant maternal and fetal mortality of approximately 6% and 14% to 30%, respectively, and should be avoided when possible (132,133). Fetal risk is increased in part by provocation of uterine contractions in association with extracorporeal circulation. Maternal hypotension and consequent placental hypoperfusion contribute as well, these factors conspiring to promote fetal hypoperfusion, hypoxia, and bradycardia. Fetal mortality at maternal cardiac surgery has been reported to vary with factors such as maternal age >35 years, maternal functional class, reoperation, emergency surgery, the type of myocardial protection, and anoxic time (134). To minimize fetal risks, tailored anesthetic and bypass techniques can be used during cardiac surgery (135). In some circumstances, cardiac surgery can be combined with elective caesarean delivery immediately before bypass.

MANAGEMENT ISSUES DURING LABOR AND DELIVERY

In our center, caesarean delivery is favored only in women who have aortic dissection or Marfan syndrome with dilated aortic root or if there has been a failure to switch from warfarin to heparin at least 2 weeks prior to labor. In essentially all other circumstances, vaginal delivery is preferred in the absence of obstetric contraindication. At our institutions, rates of caesarean deliveries in women with heart disease are the same as those in women without heart disease (136). Preterm induction of labor is rarely indicated. There is an association between antepartum adverse cardiac events and premature labor and delivery (41). Induction of labor is generally safe in women with heart disease (137). Subcutaneous administration of unfractionated heparin should be discontinued at least 12 hours prior to induction of labor or reversed with protamine if spontaneous labor develops. LMWH cannot be reversed with protamine and needs to be discontinued earlier or switched to unfractionated heparin for the last stage of pregnancy. Epidural anesthesia with adequate volume preloading is the anesthetic technique of choice. Epidural fentanyl, which does not lower peripheral vascular resistance, is particularly advantageous in cyanotic patients with shunt lesions or in patients with significant aortic stenosis. Air and particulate filters should be placed in all intravenous lines in women with intracardiac shunts. The use of invasive hemodynamic monitoring during labor and delivery must be individualized. For instance, intra-arterial monitoring and central venous pressure monitoring may be used in cases where there are concerns about the interpretation and deleterious effects of a sudden drop in systemic blood pressure (e.g., patients with severe aortic stenosis, pulmonary

hypertension, severe systemic ventricular systolic dysfunction, or preload-dependent physiology such as seen after a Fontan operation). Pulmonary artery catheters are utilized only in the extremely rare situations where the information sought is not available otherwise and warrant the risk of the procedure. At our institution, there has been a major decline in the use of arterial lines and use of pulmonary artery catheter for labor and delivery (136). Labor can be conducted in the left lateral decubitus position to attenuate hemodynamic fluctuations associated with uterine contractions in the supine position. Forceps or vacuum extraction will reduce need for maternal expulsive efforts during the latter part of the second stage of labor. The 2007 American Heart Association Prevention of Infective Endocarditis guideline do not suggest endocarditis prophylaxis for uncomplicated vaginal deliveries (138). The 2008 American Heart Association/American College of Cardiology Guideline for the Management of Adults With Congenital Heart Disease states that there is no consensus on endocarditis prophylaxis at the time of delivery and suggests that it may be used in the same high-risk groups for which antibiotic prophylaxis should be administered prior to dental procedures (139).

The hemodynamic changes of labor and delivery often do not return to baseline levels for many days after delivery; therefore, high-risk women may require additional monitoring postpartum. The mortality risk persists for at least a week in women with Eisenmenger syndrome who therefore require extended postpartum observation.

CONTRACEPTION

Contraception planning is important and age-appropriate counseling should begin in early adolescence. Choice of contraceptive method needs to be individualized and should take into account patient safety specifically regarding thromboembolic risk, patient preference, efficacy, and the consequences of contraceptive failure (140,141). Studies pertaining to risk in women with congenital heart disease are not available so contraceptive safety is extrapolated from safety profiles determined in women without heart disease. Recommendations for the use of estrogen-containing contraceptives in women with heart disease are shown in Table 69.3 (140). Low-estrogen oral contraceptives are highly effective, but should be used only in women with a low to moderate thrombotic risk. Estrogen-containing contraceptive therapy is also contraindicated in women with thromboembolic disease, undiagnosed abnormal genital bleeding, acute liver disease, liver tumors, or known or suspected breast carcinoma. For patients with higher thromboembolic risk, progestin-only contraceptive pills ("mini-pill") or other progesterone-containing contraceptives such as long-acting medroxyprogesterone acetate injection (Depo-Provera™) or levonorgestrel implant (Norplant™) may be suitable options. Barrier methods have few complications, but are associated with high failure rates compared to other forms of contraception, hence unsuitable as the sole method if pregnancy is to be avoided. Intrauterine devices, such as Mirena™ levonorgestrel-releasing intrauterine device, are best suited for women in monogamous relationships after childbearing years because of the risk of pelvic inflammatory disease. Sterilization may be considered in select cases when the risk of pregnancy is prohibitive or childbearing has been completed. In the absence of systematic data examining contraception in women with congenital heart disease, the above recommendations and Table 69.3 represent a starting point for discussion. If a woman is not in a low-risk group, consultation with a gynecologist with expertise in caring for women with heart disease is advised.

TABLE 69.3

Risk Classification for the Use of Combined Hormonal Contraceptive in Women with Congenital Heart Disease

WHO 1 Always useable Condition with no restriction for the use of the contraceptive method	WHO 2 Broadly useable Condition where the advantages of the method generally outweigh the theoretical or proven risks	WHO 3 Caution in use Condition where the theoretical or proven risks usually outweigh the advantages of using the method	WHO 4 Do not use Condition that represents an unacceptable health risk if the contraceptive method is used
<ul style="list-style-type: none"> ■ Mitral valve prolapse with trivial mitral regurgitation ■ Bicuspid aortic valve with normal function ■ Mild pulmonary stenosis ■ Repaired coarctation with no hypertension or aneurysm ■ Simple congenital lesions successfully repaired in childhood and with no sequelae (atrial or ventricular septal defect, PDA or total anomalous pulmonary venous drainage) 	<ul style="list-style-type: none"> ■ Most arrhythmias other than atrial fibrillation or flutter ■ Uncomplicated mild native mitral and aortic valve disease ■ Tissue prosthetic valve lacking any of the features noted in WHO 3 or 4 columns ■ Surgically corrected congenital heart disease lacking any of the features noted in WHO 3 or 4 columns ■ Small left-to-right shunts not reversible with physiologic maneuvers (i.e., small VSD, small PDA) ■ Hypertrophic cardiomyopathy lacking any WHO III or IV features ■ Past cardiomyopathy, fully recovered, including peripartum cardiomyopathy ■ Uncomplicated Marfan 	<ul style="list-style-type: none"> ■ Atrial fibrillation or flutter even on warfarin ■ Bileaflet mechanical valve even on warfarin ■ ASD with left-to-right shunt that may reverse with physiologic stress (i.e., Valsalva maneuver) ■ Repaired coarctation with aneurysm and/or hypertension ■ Previous thromboembolism 	<ul style="list-style-type: none"> ■ Atrial fibrillation or flutter, if not anticoagulated ■ Bjork Shiley or Starr Edwards valve even if taking warfarin ■ Fontan circulation even if on warfarin ■ Cyanotic heart disease ■ Pulmonary arteriovenous malformation ■ Prior left ventricular dysfunction from any cause (i.e., dilated cardiomyopathy) (LVEF <30%) ■ Coronary artery disease ■ Coronary arteritis (i.e., Kawasaki disease with coronary involvement)

WHO—World Health Organization contraception classification.

Other Special Problems and Issues

Chest Pain in Children and Adolescents

Jonathan N. Johnson ■ David J. Driscoll

Chest pain is a common presenting symptom in children and adolescents. In prospective studies, it has been shown to occur at a rate of 0.25% to 0.6% of visits both in the outpatient setting and the emergency department (1–3). Chest pain accounts for 650,000 physician visits per year in patients 10 to 21 years of age (4). Awareness of both cardiovascular disease and the risk of sudden cardiac death has increased both in media and in national education programs. In fact, >50% of adolescents with a history of chest pain report significant fear of cardiac pathology (5). Fortunately, chest pain in children and adolescents is rarely cardiac in nature; cardiac causes typically account for fewer than 5% of chest pain cases in published studies (Table 70.1) (1–3). The mean age of children and adolescents who complain of chest pain is 11 to 14 years, but chest pain can occur in children as young as 4 years of age (1,6). Chest pain is equally common in males and females, although certain etiologies may have a sex-specific predilection.

The relative frequencies of types of chest pain have been reported by several investigators and are summarized in Table 70.2, and are described below. The most common source of chest pain in children and adolescents is the musculoskeletal structures of the chest wall (1,2,4–9).

MUSCULOSKELETAL/CHEST-WALL PAIN

Costochondritis

Costochondritis is a common cause of musculoskeletal chest-wall pain, particularly in adolescent patients (10). The onset of the pain may be preceded by a respiratory illness, although the exact etiology is unknown. The pain typically involves two to four contiguous costochondral or costosternal junctions, between the second and fifth costal cartilages (1,10). The joints are not inflamed, and there is no swelling of the joints. The pain is most commonly unilateral and may affect the left side more frequently than the right. The patient will complain of a sharp pain lasting from several seconds to several minutes, which is exacerbated by deep breathing. Direct palpation of

the affected joint(s) will reproduce the pain. The patient may describe a “burning” sensation for a few minutes after deep palpation. It is important to apply sufficient pressure during this palpation, as light touch may not reproduce the pain. Costochondritis is typically self-limited (11). Treatment consists of reassurance and rest from athletic or strenuous activities, and occasionally may require the use of nonsteroidal anti-inflammatory medications, at least in the acute phase.

Tietze Syndrome

Tietze syndrome involves the inflammation of a single costochondral junction (12). While this syndrome has been reported in children and even infants, it remains relatively uncommon in childhood (12). The affected joint will be swollen and tender to palpation, and may be warm to the touch. Its etiology is unknown. The pain is typically self-limited, lasting anywhere from a few weeks to a few months. When necessary, nonsteroidal anti-inflammatory medications can be used.

Idiopathic Chest-Wall Pain

Nonspecific (idiopathic) chest-wall pain is the most common type of chest pain in children and adolescents (Table 70.2). The pain is described as sharp, lasting several seconds to several minutes. The pain often is exacerbated by deep breathing, and may occur during exercise or while at rest. It is most often located in the center of the chest or just below the breast. Sometimes, squeezing the chest cage or gently pressing on the sternum can reproduce the pain. More frequently, the pain cannot be reproduced by palpating and pushing on various chest structures, but the costochondral and costosternal joints are not tender. There are no associated symptoms, but patients may feel anxious while experiencing the pain (13). Most patients are able to continue activities despite the pain. Children with idiopathic chest pain tend to have longer courses than children with other etiologies and may have intermittent chest pain for many months (16,14). A thoughtful explanation of the cause and benign nature of the pain frequently is enough to reassure the patient with idiopathic chest-wall pain.

 Breast tenderness
 Idiopathic chest-wall pain

Precordial Catch Syndrome

Precordial catch syndrome is a brief (several seconds), sharp, stabbing pain occurring in healthy children, most commonly in patients between 6 and 12 years of age (15). The pain typically is located below the left breast or at the lower left sternal border (15,16). It frequently is pleuritic in nature, worsening with deep inspiration. It also may worsen when the patient bends forward. The pain can be so sharp that the patient will breathe shallowly for several seconds. It can occur at rest or with exercise. When it occurs during exercise, the patient may have to stop and breathe shallowly until the pain subsides. The patient is able to resume activities immediately after pain resolution. The physical examination typically is unremarkable. The etiology is unknown. Treatment typically is unnecessary and ineffective, due to the random nature of the pain (15).

Slipping-Rib Syndrome

Slipping-rib syndrome involves the 8th, 9th, and 10th ribs, which do not attach directly to the sternum (17,18). Instead, they attach to each other via dense fibrous tissue. In many cases, there is a history of trauma to the area, which results in disruption of these intercostal connections. This can result in rib laxity, pressure on intercostal nerves, and a “popping” sensation (19). Subsequently, any form of activity that causes these tissues to move (coughing, athletics, stretching) will produce or worsen the characteristic intense aching pain (17). The characteristic exam finding in slipping-rib syndrome is the “hooking maneuver.” This is performed by the examiner putting his or her fingers under the inferior rib margin and pulling anteriorly. This action will reproduce the pain and may produce a clicking or popping sound (17). Treatment options for slipping rib syndrome primarily include rest and

nonsteroidal anti-inflammatory medications. In difficult cases, local anesthetic blocks can be performed. Surgical resection of the specific cartilages can be performed but should be reserved only for severe cases (17,18).

Hypersensitive Xiphoid Syndrome

Hypersensitive xiphoid syndrome is a rare form of chest pain in children (20). Patients may present with sternal pain that can radiate to the shoulders, back, arms, or precordium. In these patients, gentle digital pressure on the xiphoid process will reproduce the pain. Treatment is typically unnecessary.

Trauma and Muscle Strain

Chest pain often can be caused by traumatic injury to the chest wall, particularly in athletes. The history of prior trauma is suggestive, and typically the pain is reproducible with palpation of the affected area of the chest. The pain often is worsened with positioning or activities involving the specific muscle and bony tissues (13). For simple muscle strains, nonsteroidal anti-inflammatory medications are typically effective. The examiner must be aware that significant trauma can produce a myocardial contusion and possibly a hemopericardium (see Chapter 23), both of which can cause chest pain. Significant trauma requires full evaluation for potential bony and visceral injuries.

OTHER NONCARDIAC CAUSES OF CHEST PAIN

Although musculoskeletal chest-wall pain is the most common cause of chest pain in children and adolescents, there are many

other, less common, causes of chest pain. These include the following.

Pulmonary

Asthma and exercise-induced asthma are well-known causes of chest pain in children and adolescents. Laboratory evidence of asthma has been detected in up to 73% of children evaluated for chest pain, although this is likely an overrepresentation (21). Nonetheless, reactive airway disease should be considered in patients with chest pain, particularly if there is a history of asthma, eczema, allergies, shortness of breath with exercise, exercise-associated chest pain, exertional cough, wheezing, or a family history of asthma. Chest pain in patients with asthma most likely is secondary to cough, chest-wall muscle strain, or dyspnea/hyperinflation (19). Exertional asthma can be treated with inhaled bronchodilators prior to initiation of activities.

Pneumonia can be a cause of chest pain, particularly if there is pleural or diaphragmatic irritation (19). Additionally, pleural effusions or localized empyemas may produce localized chest pain. In addition to pneumonia/pneumonitis, infection of the large airways may cause chest pain, including bronchitis and tracheitis. These patients often present with other concurrent typical symptoms to help clarify the diagnosis. Finally, the physician should ask of any possible ingestion history, as the presence of a foreign body in the airway may produce dyspnea and chest pain.

Pulmonary embolism is extremely rare in children (22). However, it requires consideration in patients presenting with chest pain who have a history of clotting disorders, venous thromboembolism, Klippel-Trenaunay syndrome, concurrent

malignancy, recent surgery, or who are taking oral contraceptive medications.

Herpes Zoster

Herpes zoster can produce intense localized sharp chest pain. The pain is caused by an intercostal neuralgia and may present before the appearance of the characteristic skin eruption. Worsening of the pain may occur with movement and deep breathing. The pain typically resolves with healing of the skin lesions; however, postherpetic neuralgia may persist and be quite painful. In these cases, neuromodulating pain medications like gabapentin may be helpful. Local anesthetic blocks can be performed in severe cases.

Sickle Cell Disease

Patients with sickle cell disease can develop a vaso-occlusive crisis that includes chest pain ("acute chest syndrome") and an infiltrate on chest radiography. The pain can be secondary to several processes, including infarction of bony structures, intercostal muscles, and lung tissue from microvascular occlusion. A patient suspected to have acute chest syndrome should be evaluated emergently (23).

Pericarditis

Pericarditis, whether due to an infectious etiology or a noninfectious inflammatory cause, is associated with chest pain. The pain associated with pericarditis is generally more severe than that of benign forms of chest-wall pain. Children may describe

the pain as squeezing, sharp, or dull. It may be intensified by lying down. Patients often will sit with a forward lean, which alleviates the pain. The pain is worse with inspiration, coughing, and movement (24).

The pathognomonic physical finding is a friction rub: a high-frequency, scratching/sandpaper-like sound caused by friction between the inflamed pericardial surfaces. It is best heard at the left sternal border or apex and is loudest when the heart is closest to the chest wall (when the patient leans forward, kneels, and inspires). Muffled heart sounds suggest the presence of a large pericardial effusion (24). Pericarditis is associated with typical electrocardiographic findings of generalized ST-segment elevation. Echocardiography may be helpful in diagnosis (see Chapter 62).

Gastrointestinal

Gastrointestinal disorders are a common cause of chest pain, particularly in adolescents and adults. The most common causes are esophagitis (reflux, pill related, and eosinophilic) and gastritis. Symptoms often are difficult to discern from cardiac or chest-wall pain. Pain associated with food ingestion or associated with dysphagia may indicate a gastrointestinal cause (19).

Pneumothorax/Pneumomediastinum

Among patients with chest pain, pneumothorax or pneumomediastinum are uncommon; however, these conditions are always associated with chest pain (25). Small air collections may be difficult to detect by clinical examination. The abrupt onset of severe chest pain should alert the clinician to this potential diagnosis. Particular consideration for a pneumothorax should be given to patients with Marfan syndrome who develop sudden-onset chest pain or dyspnea. Chest radiography is diagnostic.

Psychogenic

Chest pain secondary to psychogenic etiologies is a diagnosis of exclusion, requiring a full evaluation for potential life-threatening causes. It has a higher incidence in teenagers, particularly in females. There often is a trigger for the onset of the pain, including recent psychologic and emotional stress, or recent diagnosis of another organic disease. Psychogenic chest pain is more common in patients with a family history of cardiac disease (26). The physical examination is normal. Treatment is difficult, and includes extensive reassurance and treatment/counseling for their underlying psychiatric concerns.

Anxiety-related hyperventilation also can cause chest pain. Physiologically, this occurs secondary to respiratory alkalosis and subsequent coronary artery vasoconstriction (27). Treatment involves referral to a physiotherapist, who can help the patient learn specific breathing techniques to prevent the dysfunctional breathing patterns.

CARDIAC CAUSES OF CHEST PAIN

In a population of children and adolescents with chest pain, the proportion with a cardiac origin for the chest pain is extremely low. Some cardiac conditions, however, are associated with chest pain. These include obstructive hypertrophic cardiomyopathy, aortic stenosis, pericarditis, arrhythmias, coronary insufficiency, dissecting aortic aneurysm (especially in patients with Marfan syndrome), and mitral valve prolapse.

Causes of coronary insufficiency in children include Kawasaki disease, Williams syndrome, anomalous origin of the coronary arteries, and coronary arteriovenous and coronary cameral fistulae. These conditions are reviewed in other chapters of this textbook. Additionally, it is critical to ask about recent medication and drug intake, particularly substances that may induce coronary vasospasm.

Even in a population with these conditions, chest pain is an uncommon presenting symptom. It is important to identify patients who are at high risk for these conditions through historical information and characteristics of the pain so that appropriate diagnostic and therapeutic steps can be taken. A recent study reported the experience at the busy outpatient clinics at Children's Hospital Boston of patients aged 7 to 21 years. In a 10-year period, only 41 patients with an initial presentation of chest pain were ultimately determined to have a cardiac cause (28). Only 32 of these were considered to have serious cardiac pathology. Patients with coronary anomalies and chest pain are far more likely to present to an outpatient clinic, while patients with chest pain secondary to myocarditis, pericarditis, or pulmonary embolism are more likely to present to an emergency department or inpatient setting (28).

MEDICAL EVALUATION

The evaluation of chest pain requires a thorough history and careful physical examination (1,13). The family history should be explored for premature forms of heart or lung disease and instances of premature death. Particular inquiry should be made as to a family history of unexplained drownings, car accidents, syncope, and sudden infant death syndrome (SIDS). In addition, it may be helpful to know whether other family members have chest pain, such as a parent or grandparent who experiences angina.

In the majority of cases, the cause of the pain will be apparent after the history and physical examination. Most patients will not have a serious underlying medical problem, but the patient and the patient's family may think they do (5). A thorough and thoughtful history and physical examination are important in reassuring the patient and family that there is no serious problem. The examination should include a full heart, lung, extremity, and abdominal exam. It is important to palpate the costochondral joints and other areas of the chest to try to elicit localized tenderness.

Few patients truly have angina. If, however, a history of angina is elicited, appropriate testing will be needed. A history of chest pain associated with presyncope, syncope, sweating, nausea, palpitations, cyanosis, or dyspnea should make raise suspicion of a potentially serious underlying cause of the chest pain. Additionally, a history of chest pain with exercise should be evaluated further. A strong family history of sudden death, aortic dissection, or cardiomyopathy also may prompt further evaluation despite an equivocal personal history.

In the vast majority of cases of chest pain in children, only a history and physical examination are necessary and additional tests are not particularly helpful (1,2,28). In the unusual circumstance where cardiac disease is strongly suspected, several investigations may be performed. An electrocardiogram may be performed to assess for heritable arrhythmia disorders including preexcitation. Chest radiography can assess for heart size, effusions, and pulmonary processes. An echocardiogram can be performed to assess for structural heart disease, cardiomyopathy, and coronary anomalies. Exercise stress testing can assess for exercise-induced ST-segment changes, exercise-induced arrhythmias or ectopy, and overall cardiovascular conditioning.

TREATMENT

The specific treatment of chest pain depends on the underlying cause. For most patients with musculoskeletal causes of chest pain, an explanation of the cause of the pain and its benign nature frequently is enough to reassure the patient and their family. The goal in these discussions is to reduce the anxiety associated with the pain, allowing the patient to tolerate the pain better with less fear. Children with noncardiac chest pain have been reported to have more symptoms of anxiety as compared to children with cardiac causes of chest pain (29). The use of medication is usually unnecessary for the majority of causes of chest-wall pain. If necessary, mild doses of non-steroidal anti-inflammatory medications are often sufficient. If history and physical examination suggest a cardiac cause, appropriate consultation and evaluation should be sought.

OUTCOME

The long-term outcome of chest pain in children is generally very good. Driscoll et al. (1) found resolution of chest pain in 58% of patients when questioned 4 weeks to 2 years after initial evaluation of their chest pain. Lam et al. (30) reported that almost half (49%) of patients had recurrence of their chest pain. However, 12 of 26 patients with recurrent chest pain had pain only occasionally on follow-up. Selbst et al. (9) reported 6-month follow-up on 149 patients who had presented with chest pain. They noted that the initial diagnosis was changed in 34% of the patients on follow-up, typically indicating a nonorganic cause of the chest pain. A new organic cause was found in only 12/149 (8%) patients. Only one child was found to have evidence of cardiac pathology, mitral valve prolapse. The pain resolved in 57% of patients. Pain lasting longer than 6 months is more likely due to an idiopathic or psychogenic etiology (1,2).

ATHEROSCLEROSIS

Coronary artery disease and stroke are the most common causes of morbidity and mortality in developed countries. The breakdown of the prevalence of different cardiovascular diseases in the United States is presented in Figure 71.1. It can be seen that coronary heart disease and stroke constitute 68% of cardiovascular diseases in the United States with coronary heart disease accounting for 51% alone.

Clearly, this is an important public health problem. In the past, atherosclerosis has been viewed as a problem of adults and not a focus in the pediatric age range. This is because the clinical manifestations of atherosclerosis are often not observed until middle age. However, there is increasing evidence that the process of atherosclerosis begins in childhood and is progressive throughout life.

Atherosclerosis results from deposits of lipid and cholesterol in the intima of the arterial wall. The earliest abnormality is thought to be the fatty streak (Fig. 71.2). This is an accumulation of lipid-filled macrophages within the intima (1). These lesions are flat and do not obstruct the arterial lumen. The natural history of these lesions is that some progress to raised plaques. This is a result of continued lipid accumulation and a proliferation of macrophages and smooth muscle cells (2). In this lesion, smooth muscle-type cells form a fibrous cap over a deposition of necrotic debris, cholesterol crystals, and ultimately calcification within the arterial wall. It is these raised lesions that result in a myocardial infarction because of either their increasing size and obstruction of the arterial lumen or their rupture, which results in the release of thrombogenic substances from the necrotic core. It has been noted that the fibrous plaques tend to develop at the anatomic site where fatty streaks are formed in children (3). Plaques generally tend to develop in the coronary arteries prior to their appearance in the cerebral arteries.

The early stages of the atherosclerotic process are asymptomatic. The best understanding of this process has come from a series of pathology studies. The earliest pathology studies were performed during the Korean War and the war in Vietnam (4,5). The results of these studies were somewhat surprising in that young and healthy males were found to have both fatty streaks and raised lesions. Although these early pathology studies documented the presence of atherosclerosis, they did not establish the risk factors for the early stages of this process. This information would come from subsequent studies.

There has been substantial epidemiologic research on the risk factors for cardiovascular disease development in adults. Longitudinal studies such as the Framingham study have measured potential risk factors and followed subjects to the development of cardiovascular disease. In fact, investigators have proposed >200 potential risk factors for the development of coronary artery disease. Most of these proposed risk factors have come from cross-sectional correlation studies. However, establishing a causal relationship is substantially more

difficult. This requires multiple studies including some with a longitudinal design with follow-up to the cardiovascular end point. It has also been difficult to establish the independence of a particular risk factor because often associations exist among risk factors. After decades of research, a group of risk factors, often referred to as the traditional risk factors, has been established. These risk factors are presented in Table 71.1. As can be seen, some of the risk factors are potentially modifiable and others are not. Table 71.2 lists novel factors that have strong consideration but are not yet considered established as independent risk factors.

The risk factors for the early aspects of the process of atherosclerosis have been determined by the more recent pathology studies including the Bogalusa study and the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study. The PDAY study was a multicenter investigation of individuals aged 15 to 34 years who died of accidental causes and suicide unrelated to the known presence of cardiovascular disease (6,7). The investigators performed autopsies to evaluate the extent of atherosclerosis in the aorta and coronary arteries. They used various indicators of risk factor status obtainable at the time of autopsy to define risk. They found that the traditional risk factors, including dyslipidemia, blood pressure elevation, and obesity, were associated with the presence of fatty streaks and of fibrous plaques.

The Bogalusa study investigators were able to obtain autopsies in individuals who had been participants in a school-based risk factor study, were followed longitudinally, and died of accidental causes (8,9). The investigators in the Bogalusa study found that the percent of the surface of the arteries covered with fatty streaks and fibrous plaques increased with increasing age at the time of death. They also found that the extent of coverage of the arteries (aorta and coronary arteries) was associated with elevation of total cholesterol, low-density lipoprotein cholesterol (LDL-C), triglycerides, blood pressure, and body mass index (BMI) during the school-age surveys. A low high-density lipoprotein cholesterol (HDL-C) was also associated with a greater extent of coverage of the arterial surface with fatty streaks and fibrous plaques. An additional important finding was that the prevalence of atherosclerosis increased with an increasing number of risk factors present. This was particularly true for fibrous plaques in the coronary arteries where the presence of three or four risk factors was associated with 7% coverage and the presence of one or two risk factors was associated with 1% and 2% coverage, respectively (9).

Imaging

One factor that has made the study of atherosclerosis difficult is the lack of noninvasive tools to image the early atherosclerotic lesions. In adults, computed tomography (CT) scanning has been used to detect the presence of calcium in the coronary arteries. The presence of calcium deposits has been associated

Figure 71.1. Prevalence of cardiovascular disease in the United States. (From Lloyd-Jones D, Adams RJ, Brown TM, et al. Heart Disease and Stroke Statistics—2010 Update: A Report From the American Heart Association. *Circulation* 2010;121:e46–e215, with permission.)

Figure 71.2. A: Gross anatomic specimen of the abdominal aorta. Fatty streaks, the earliest evidence for atherosclerosis, are seen as white strands through the tissue. B: Photomicrograph (original magnification $\times 0$) of fatty streak using Sudan black stain. The vacuolization is caused by the fat globules of the lesion. C: Gross anatomic specimen of the origin of the left coronary artery. A complex lesion (plaque) of calcium, fibrous tissue, and fat fills the vessel. D: Photomicrograph (original magnification, $\times 100$) of coronary artery plaque using hematoxylin and eosin stain. This complex raised lesion shows erosion of the endothelium, clot, and cholesterol clefts. with increased risk for adverse cardiovascular disease outcomes (10). Fewer studies have evaluated this issue in young subjects. Investigators from the Muscatine Study used electron beam CT to evaluate young adults who had participated in a longitudinal epidemiologic study of cardiovascular risk factors as children (11). The subjects were younger than 35 years of age. The prevalence of coronary artery calcium was 31% in men and 10% in women.

The investigators also evaluated the extent to which risk factors were associated with the presence of coronary artery calcium. They found that the risk factors measured most recently were the strongest predictors including systolic blood pressure, BMI, LDL-C, and HDL-C. However, weight in childhood and BMI, diastolic blood pressure, and cholesterol in young adulthood were also associated with increased risk of calcium in the coronary arteries (11).

Gidding et al. (12) studied a group of adolescents and young adults aged 11 to 23 years with heterozygous familial hypercholesterolemia. They found that 7 of 29 subjects had coronary artery calcium. Calcium was more likely to be present when obesity and cholesterol elevation were both present.

Magnetic resonance imaging (MRI) may also be used to evaluate the atherosclerotic process. It has been used to evaluate the presence of atherosclerotic plaques and supraaortic stenosis in young patients with homozygous familial hypercholesterolemia (13). Studies in adults have also demonstrated that high-resolution multicontrast MRI can be used to evaluate whether arterial plaque is unstable and subject to

rupture (14). This is important as other noninvasive methods have been unable to characterize this progression of atherosclerosis. This method allows the fibrous cap to be distinguished from the lipid core. It is not currently known if MRI will be useful in following the evolution of fatty streaks to fibrous plaques.

Ultrasound methodology has also been used to evaluate the presence of atherosclerosis. In adults, the measurement of the carotid artery intima-media thickness (IMT) has gained acceptance as a useful method in epidemiologic studies to evaluate atherosclerosis. In adults, it has been shown that increased carotid IMT is associated with cardiovascular risk factors (15) and with incident myocardial infarction (16) and stroke (17). However, in a meta-analysis of 41 randomized clinical trials, Costanzo et al. (18) found that regression or slowed progression of carotid IMT induced by cardiovascular drug therapies in adults does not reflect reduction of cardiovascular events. Fewer studies have used ultrasound to evaluate carotid IMT in children and adolescents. Davis et al. (19) studied the young adult Muscatine population aged 33 to 42. These were individuals who had participated in the school surveys when they were younger. In males, childhood total cholesterol and triglycerides were higher in those with elevated carotid IMT. In females, childhood weight, BMI, total cholesterol, and triglycerides were higher in those with high carotid IMT. The Young Finns study had a similar design (20). In multivariable models adjusting for age and sex, they found that childhood LDL-C, systolic blood pressure, BMI, and cigarette smoking were associated with increased carotid IMT in young adulthood. Sanchez et al. (21) performed a study of high school students. They found relationships between LDL-C, HDL-C, systolic blood pressure, diastolic blood pressure, and BMI with carotid artery IMT. Other studies have also found that children with elevated cholesterol levels have significantly elevated carotid artery IMT compared with controls (22). Sorof et al. (23) evaluated 32 children with hypertension. They found a significant association between carotid artery IMT and left ventricular mass after adjustment for age, sex, and BMI. In those patients with hypertension and increased carotid artery IMT, the prevalence of left ventricular hypertrophy was 89% compared with 25% in those with normal carotid artery IMT. Jarvisalo et al. (24) reported a significant association between C-reactive protein (CRP), which is a marker of inflammation, and carotid artery IMT. They also found an association between elevated CRP and impaired brachial artery flow-mediated dilation, which is a measure of endothelial function.

Juonala et al. (25) studied the relationship of cardiovascular risk factors measured in childhood with carotid IMT in adulthood in four large cohort studies: the Cardiovascular Risk in Young Finns Study, the Childhood Determinants of Adult Health Study, the Bogalusa Heart Study, and the Muscatine Study. They found significant relationships between childhood risk factors and adult carotid IMT that were dependent on the age at which childhood risk factors were measured. These data demonstrated that risk factor measurements obtained at age 9 years or older are predictive of subclinical atherosclerosis in adulthood.

Thus, it does appear that evaluation of the carotid arteries using ultrasound is a useful marker of preclinical atherosclerosis in children and adolescents (26). This method is currently used only in the research setting, but as it is studied in more detail, it may also ultimately be useful as a clinical test. In the meantime, other modalities are being investigated and may prove useful in the future.

Risk Factors for Atherosclerosis

Several risk factors have been established as being important in the development of atherosclerosis and ultimately in

TABLE 71.2 Possible Risk Factors for Atherosclerosis and Coronary Artery Disease

Inflammation
Elevated CRP

Diet

the occurrence of myocardial infarction and cerebrovascular disease. Dyslipidemia and hypertension are reviewed in detail in Sections “Lipids and Lipoproteins” and “Hypertension”. Other risk factors are discussed here briefly.

Diabetes

Diabetes is well established as a major risk factor for cardiovascular disease in adults (27). In the past, most pediatric patients with diabetes had type 1 diabetes mellitus. This was different from the experience with adults in whom the prevalence of type 2 diabetes mellitus was much higher. However, with the increasing prevalence and severity of obesity in the pediatric population, the prevalence of type 2 diabetes has increased dramatically (28). This is of critical importance from the standpoint of cardiovascular disease development. In adults, type 2 diabetes is responsible for more cases of renal failure and peripheral vascular disease than any other disease process (29). The risk of cardiovascular disease in patients with diabetes is increased by as much as fivefold compared with individuals without diabetes (30). It has been estimated that 70% of adult patients with type 2 diabetes die of cardiovascular disease (31), and the 10-year mortality rate for patients with type 2 diabetes is approximately 10 times higher than in a nondiabetic comparison group, with most deaths occurring as a result of coronary artery disease (32).

The predisposition to cardiovascular disease in patients with diabetes cannot be overemphasized. This is underscored by the recommendations of the American Diabetes Association (33) and the National Cholesterol Education Program (NCEP) (34), which consider the presence of diabetes to be a coronary artery disease risk equivalent. This means that patients with diabetes should be treated with the same aggressive approach to risk factor management that would be recommended in a patient who already has established coronary artery disease or who has had a myocardial infarction.

The risk status for cardiovascular disease in adolescents with type 2 diabetes is not well understood. However, if the progression of atherosclerosis is similar to that seen in adults, it can be anticipated that these patients may develop clinically apparent cardiovascular disease as early as their late thirties and early forties. Unfortunately, because so little is known about the progression of cardiovascular disease in young patients with type 2 diabetes, it is difficult to make evidence-based decisions regarding the optimum clinical strategies to prevent cardiovascular disease.

Some results regarding the relationship of diabetes and cardiovascular abnormalities have begun to emerge. Shah et al. (35) evaluated cardiac structure and function in adolescents with type 2 diabetes and those with obesity alone. They found that adolescents with obesity and with obesity-related type 2 diabetes had changes in cardiac geometry consistent with cardiac remodeling. Both groups also had decreased diastolic function when compared to lean controls with the greatest decrease in those with type 2 diabetes.

Urbina et al. (36) reported increased arterial stiffness, a marker for the development of atherosclerosis, in both adolescents with obesity and those with type 2 diabetes mellitus after controlling for other risk factors. Wadwa et al. (37) studied adolescents with type 1 and type 2 diabetes mellitus. They found that youth with type 2 diabetes had increased arterial stiffness compared to those with type 1 diabetes. In their study, increased central adiposity and blood pressure were associated with increased arterial stiffness independent of the type of diabetes. Urbina et al. (38) studied carotid IMT and stiffness in relation to obesity and type 2 diabetes and found that abnormalities in carotid thickness and stiffness are only partially explained by traditional cardiovascular risk factors. This suggests that more

research is needed to understand additional factors that may be related to this process. Shah et al. (39) reported that longer duration of diabetes and poorer glycemic control both have an independent association with carotid IMT in adolescents with type 2 diabetes. These results emphasize the need for improved blood glucose control to prevent the progression of cardiovascular disease in patients with type 2 diabetes.

Additional research will be needed to better define the optimum clinical approaches to young patients with type 2 diabetes. Nevertheless, it is important to manage the diabetes with appropriate weight management and blood glucose control methods. It is also important to evaluate cardiovascular risk factors in patients with diabetes and treat those risk factors when present.

Cigarette Smoking

Cigarette smoking is a major independent risk factor for cardiovascular disease (40). Although prevention of cigarette smoking is of the greatest importance, it has also been shown that cessation of smoking can provide a benefit by reducing risk of cardiovascular and lung disease. Investigators from the Multiple Risk Factor Intervention Trial (MRFIT) have reported that cessation of smoking will reduce the risk of the development of cardiovascular disease (41). This reduction of risk begins in the first year after cessation and continues to further reduction as long as 3 years after cessation.

In adolescents, atherosclerotic lesions have been seen with increased prevalence in cigarette smokers as young as 15 years of age. In addition, LDL-C is increased and HDL-C is decreased in adolescent smokers compared with their non-smoking counterparts (42). Chronic cigarette smoking may lead to injury of the endothelium, which serves as the nidus for the development of atherosclerosis. It has been estimated that of smoking-related deaths, cardiovascular disease is involved in over one-third, and this process often begins early in life (43).

Most individuals who become regular smokers initiate cigarette smoking in childhood and adolescence. Overall, approximately one of five high school students becomes a regular smoker. Many adolescents, while experimenting with smoking, believe that they can control their use of cigarettes. Unfortunately, this is not the case as many cannot quit smoking and continue to smoke on a regular basis. During the period from 1997 to 2003, overall smoking prevalence declined in high school students from >27% to 22% (44). Unfortunately, the prevalence of smoking in girls has increased over time, so now the prevalence is closer to equal for boys and girls (45). In 2009, the prevalence of cigarette smoking in adolescent high school students was 17.2% overall, 19.6% for adolescents boys, and 14.8% for girls (46). The major influences on initiation of smoking appear to be parents and peers smoking regularly (47,48). It has been shown that parent discussion of smoking, rules against smoking, and punishment for use of cigarettes all have a beneficial effect on decreasing adolescent smoking (48,49). Of greatest importance is that adolescents are significantly less likely to initiate smoking when parents quit smoking (50). Studies have also demonstrated an inverse association between physical activity and smoking, suggesting that an increased level of physical activity may protect against smoking initiation (51). These epidemiologic study results suggest important approaches to the prevention of the onset of cigarette smoking. Efforts of prevention should begin in elementary and middle school students because many children are already experimenting with cigarette smoking by age 10 years (52).

Exposure to environmental tobacco smoke may also be associated with increased risk of cardiovascular disease. Moskowitz et al. (53) reported lower HDL-C in boys exposed to environmental tobacco smoke compared with

those who were not exposed. Weitzman et al. (54) reported a dose-response relationship between exposure to tobacco smoke measured by serum cotinine and presence of the metabolic syndrome in 12- to 19-year-olds in the National Health and Nutrition Examination Survey III (NHANES III). In this population-based cohort, the prevalence of metabolic syndrome was 1.2% for nonexposed, 5.4% for those exposed to environmental tobacco smoke, and 8.7% for active smokers (54). The prevalence of metabolic syndrome for overweight adolescents was 19.6 for those exposed to environmental tobacco smoke and 23.6 for active smokers. These results emphasize that elimination of cigarette smoking in the household may have a dual benefit by directly reducing cardiovascular risk and by decreasing the risk for initiating active smoking. One of the most striking public health results comes from studies that show that banning smoking in public places, such as restaurants and bars, resulted in a dramatic decline in cardiovascular disease mortality (55,56). These results suggest that exposure to environmental tobacco smoke has a substantial deleterious effect.

Obesity/Metabolic Syndrome

The prevalence of overweight in children has more than tripled from 1980 to 2006. The prevalence nationally is approximately 17% for both children and adolescents (57). This increase in prevalence of overweight or obesity appears to be occurring worldwide.

The Muscatine and Bogalusa studies have shown that obesity in childhood and adolescence is associated with several risk factors for cardiovascular disease including atherogenic dyslipidemia (elevated triglycerides and low HDL-C), hypertension, left ventricular hypertrophy, atherosclerosis, and obstructive sleep apnea (9,58,59). When a child or adolescent is evaluated for overweight, it is important that assessment of cardiovascular risk factors be included as part of the evaluation.

Children and adolescents should be evaluated for overweight by calculating the BMI. This should then be compared with age- and sex-specific percentiles. Obesity is defined as a BMI ≥ 95 th percentile. BMI between the 85th and 95th percentiles is considered overweight (60). Treatment of overweight is difficult but can be accomplished by behavioral, pharmacologic, and surgical approaches (61–64). The U.S. Preventive Services Task Force has performed a systematic review of pediatric weight management programs (65). They concluded that the available research supports at least short-term benefits of comprehensive medium- to high-intensity behavioral interventions in obese children and adolescents. They also found no adverse impact of comprehensive weight management programs.

Barlow et al. (66) have presented recommendations for prevention, assessment, and treatment of obesity in children and adolescents. These recommendations include a graded approach to weight management depending on the level of BMI and the presence of comorbid conditions, such as diabetes, hypertension, dyslipidemia, obstructive sleep apnea, and nonalcoholic fatty liver disease.

An important consideration with obesity is the metabolic syndrome. This is a clustering of risk factors for diabetes and cardiovascular disease that is frequently observed in patients who are overweight, particularly with an increased central distribution of fat (67). Factors that are often included in the metabolic syndrome are listed in Table 71.3. Many definitions of the metabolic syndrome have been proposed for clinical use in adults. There have also been proposed definitions for children and adolescents. Most investigators have chosen to adopt a schema similar to that used in adults but have used age- and sex-specific percentiles to define clinical cutpoints

TABLE 71.3

Factors Considered Part of the Metabolic Syndrome

Obesity (particularly central obesity)

Atherogenic dyslipidemia

↓ Triglycerides

↑ HDL-C

Hypertension

Hyperinsulinemia

Impaired glucose metabolism

Inflammation

Prothrombotic factors

(68–70). However, investigators have chosen a wide range of cutpoints. This often results in a discontinuity between the child/adolescent definition and the adult definition. As might be expected, the choice of different risk factors and different cutpoints results in very different estimates of the prevalence of metabolic syndrome. One approach has been to use the variables in the metabolic syndrome complex as continuous variables rather than defining cutpoints (71). A particular concern about the metabolic syndrome is that it appears not to be a stable diagnosis throughout adolescence with some individuals gaining the diagnosis and others losing it over time (72). Further research is necessary to determine the optimum definition of the metabolic syndrome (73). Nevertheless, clinicians should be well aware of the clustering of cardiovascular risk factors that occurs with obesity. These factors should be evaluated in the child with obesity, and the risk factors should be treated when abnormalities are found.

Physical Activity

Strong et al. (74) have evaluated the effects of physical activity on health in school-aged youth. They identified a number of cardiovascular health issues that are related to diminished physical activity. Cardiovascular fitness has been identified as a risk factor for cardiovascular disease in adults (75). Physical fitness probably has both genetic and environmental influences. Strong et al. (74) identified several correlational studies indicating an association between low levels of vigorous physical activity and low levels of cardiovascular fitness. Experimental studies showed that exercise training can improve cardiovascular fitness in children 8 years of age and older. Generally, the successful programs included continuous vigorous exercise for >30 minutes per session at a minimum of 3 days per week.

Epidemiologic studies in children have generally shown a weak association between the level of physical activity and lipids and lipoproteins. The strongest associations are usually seen with HDL-C (74). The results of studies evaluating the relationship of cardiovascular fitness to lipids and lipoproteins mostly do not show a significant correlation. Intervention studies show a weak but beneficial effect primarily in improvement of triglyceride and HDL-C concentrations, usually in the context of improvement of BMI. One of the reasons for inconsistent results is the fact that different studies used different levels of intensity of physical activity with different frequencies of exercise episodes and different durations of treatment. From the available data, it appears that a minimum of 40 minutes of activity per day 5 days per week for 4 months is required to result in lower triglyceride and increased HDL-C levels (74).

Isometric or resistance exercise may also have a benefit in raising HDL-C levels. Goldberg et al. (76) found decreased LDL-C and increased HDL-C in adolescent boys who underwent a 9-week resistance exercise training program. These improvements were not related to changes in weight or adiposity.

There is no clear association between exercise and lower blood pressure in children with normal blood pressure (74). On the other hand, in adolescents with hypertension, aerobic activity programs of 12 to 32 weeks' duration have been shown to have a blood pressure-lowering effect. Strength training appears to have little effect on blood pressure in children with hypertension.

These results suggest that children and adolescents with essential hypertension should be encouraged to engage in aerobic activity on a regular basis. It is necessary to continue the physical activity to maintain the beneficial effect. An important aspect of the impact of physical activity is that it is also useful in management of overweight. Because many cardiovascular risk factors cluster with overweight, improvement in BMI is an important mechanism of action for increased physical activity. It has been shown that programs of moderate intensity lasting 30 to 60 minutes per episode with three to seven episodes per week can lead to a reduction in both total body and visceral adiposity in children and adolescents (74). Thus, it is clear that there are numerous beneficial effects to increasing the level of physical activity in children. This may also establish better exercise habits that will last into adulthood.

Summary

There has been increasing interest in the improvement of cardiovascular health (77). There is evidence that individuals who are able to maintain low-risk status with optimum levels of cardiovascular disease risk factors through childhood, adolescence, and adulthood to age 50 have a very low lifetime risk of cardiovascular disease (78). This puts the focus on primordial prevention, which is the prevention of development of risk factors in the first place. Unfortunately, currently the prevalence of ideal cardiovascular health is quite low. Bambs et al. (79) evaluated cardiovascular health in a cohort of 1,933 individuals (mean age 59 years, 44% African American, 66% women). They found that only 0.1% met the criteria of seven risk factor

and behavioral components. Less than 10% met ≥ 5 of these components. Thus, the prevalence of ideal cardiovascular health is currently quite low in a community-based sample of middle-aged adults. While there are genetic factors involved, there are clearly behavioral and lifestyle factors that are quite important. It is increasingly clear that pediatricians, family physicians, and pediatric cardiologists must play a critical role in developing and maintaining cardiovascular health. It is also clear that achievement of this will pay great dividends.

Atherosclerosis is a slow but progressive process that begins in childhood and progresses throughout adolescence and into adulthood. There are numerous risk factors for atherosclerosis in children, which generally parallel the risk factors in adults. Pediatricians and pediatric cardiologists should take an integrated approach to the prevention of cardiovascular disease and atherosclerosis (80,81). This type of approach will be necessary for reducing death and disability from cardiovascular disease, which is the major cause of death in the United States.

LIPIDS AND LIPOPROTEINS

Lipids are organic compounds that are not soluble in water but are soluble in organic solvents. Plasma lipids are transported by lipoproteins. This combination of lipids (including cholesterol triglycerides and phospholipids) and protein (called apolipoproteins) allows the lipid component to become soluble in water and blood. Lipids are important components of cell membranes and also serve as building blocks for some hormones.

The principal apolipoproteins are A-1, A-II, B-100, and C-II. Apolipoproteins have several functions. First, they bind with specific receptor sites in cells. They also are cofactors for enzymes involved in lipid metabolism such as lecithin cholesterol acyltransferase and lipoprotein lipase. Third, they function as structural protein for the biosynthesis and secretion of plasma lipoproteins. For example, Apo A-1 has been proposed as an important structural protein for the biosynthesis of HDL.

There are four major classes of lipoproteins including chylomicrons, very low density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs) (Table 71.4).

TABLE 71.4 Lipids, Lipoproteins, and Apolipoproteins

Lipoprotein	Apolipoprotein	Source	Lipid Constituents	Factors that Influence Levels
Chylomicrons	Apo B-48 Apo A-1 Apo II Apo IV	Intestine	Exogenous triglycerides	Genetic Estrogen use, diabetes, alcohol, hypertriglyceridemia
VLDL	Apo B-100 Apo C-1 Apo C-II Apo C-III	Liver	Endogenous triglycerides, phospholipids	Genetic Excess carbohydrate, alcohol, or calories
LDL	Apo B-100	Breakdown of VLDL	Esterified cholesterol, triglycerides	Genetic Male sex, diabetes, LDL-receptor defects, intake of saturated fat and cholesterol
HDL	Apo A-1 Apo A-II Apo C-II Apo E	Liver and intestine breakdown of VLDL	Cholesterol, phospholipids	Genetic Low levels: male sex, diabetes, obesity, uremia, use of androgens or progestins, smoking; high levels: physical activity, alcohol intake

VLDL, very low density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

Chylomicrons are triglyceride-rich particles produced by the intestine. They are the largest lipoprotein. Their primary function is to transport cholesterol and triglycerides from the diet to sites for metabolism or storage (82). Chylomicrons are usually not present during fasting and normally are rapidly cleared after a meal. The clearance occurs as a result of lipoprotein lipase, which creates remnants of chylomicrons. These remnants are thought to be atherogenic and are cleared by the liver.

VLDL particles are also relatively large particles. VLDL is produced by the liver. VLDL transports triglycerides and cholesterol, which is endogenously synthesized, to the periphery (83).

LDL is the major carrier of cholesterol to peripheral tissues. LDL is made up of 45% cholesterol. LDL particles are found in atherosclerotic plaque and are associated with increased risk of cardiovascular disease (84). In particular, small dense LDL particles are considered especially atherogenic. LDL particles are recognized by specific receptors on the cell wall. When LDL particles bind to the receptor on the cell wall, they are then internalized into the cell. It has been estimated that approximately 75% of LDL particles are removed by binding with receptors, whereas the remaining particles are removed by macrophages (Fig. 71.3).

HDLs can be produced in several ways. They can be produced by the liver and the gastrointestinal tract. HDL particles are also produced by catabolism of chylomicrons and VLDL particles. HDL particles are also thought to be heterogeneous. HDL₂ is the subfraction that is thought to be most protective against atherosclerosis (85).

Normal Levels of Lipids and Lipoproteins

Normal values and distribution for plasma lipids and lipoproteins in American children have been published (86). These values have generally been used in subsequent guidelines to characterize children from a clinical perspective. These values are presented in Table 71.5.

Overall, total and LDL-C are lower in males than in females for most age groups. In children 5 to 10 years of age, HDL-C is lower in girls than in boys. It can be seen that HDL levels then gradually increase in girls and decrease in boys. The changes in concentration of lipids and lipoproteins during puberty can be important from a clinical perspective (87). LDL-C often declines during this period by as much as 10% to 20%. This means that some adolescents may experience a decline from an abnormal value to normal for a period of time. However, in the latter part of puberty, the LDL-C begins to rise and often continues to rise through adulthood.

The decline in HDL-C for males during puberty has been shown to extend into the adult ages. In young adults, HDL-C levels are approximately 10 mg/dL higher in women compared with men (88).

Epidemiology

Longitudinal studies such as the Framingham study and the MRFIT study have shown that the level of cholesterol in the blood is an important and independent predictor of coronary heart disease (89,90). It has been estimated that for each 1% increase in cholesterol, there is an approximately 3% increase in risk of cardiovascular disease (91). Studies have also consistently shown that higher levels of HDL-C are associated with a lower risk of cardiovascular disease (92).

There are international differences in levels of plasma cholesterol. In general, there are genetic and environmental influences on plasma cholesterol levels. The nutritional component most related to these differences appears to be the intake of saturated fat. In countries where intake of saturated fat in the diet is low, the blood total cholesterol levels are also low and the incidence of coronary heart disease is low (93).

Lipids and lipoproteins have been demonstrated to track over time. Tracking is an epidemiologic concept in which an individual retains their ranking with respect to their peers over time. For cholesterol, this means that, if tracking is present, a child with an elevated LDL-C will be more likely to become an adult with elevated LDL-C. Conversely, children with low levels relative to their peers will remain low over time. Epidemiologic studies of children and adolescents have shown that cholesterol levels do track, but that rank order is not maintained as consistently as it is for height and weight (94,95). In a separate analysis of the data from the Muscatine Study, Lauer et al. (96) evaluated factors that affect the relationship between cholesterol levels in childhood and adulthood. They found that cholesterol levels during childhood were important, but that obesity development, cigarette smoking, and the use of oral contraceptives in women had deleterious effects on cholesterol levels in adulthood.

Magnussen et al. (97) evaluated longitudinal data from the Childhood Determinants of Adult Health Study in which children in Australia were followed from 1985 until follow-up as young adults in 2004. They found that lifestyle changes that occur between youth and adulthood influence whether an individual maintains, loses, or develops high-risk blood lipid and lipoprotein levels in adulthood. The factors that are most important are excess weight gain, physical inactivity, and cigarette smoking.

Factors Causing Dyslipidemia

Genetic

Lipid synthesis and metabolism is quite complex. Because there are numerous steps in the processes, they are vulnerable to genetic abnormalities that lead to dyslipidemia.

The most important and well-understood genetic abnormality is familial hypercholesterolemia. Brown and Goldstein (98) have described the LDL-C receptors that are associated with familial hypercholesterolemia. They have now described numerous mutations of the genes for the LDL receptor, which is a membrane glycoprotein. The most common LDL-C receptor gene mutations often result in a situation where the LDL receptor protein is produced only in small amounts. Other mutations result in the synthesis of precursors of the receptor that are not converted to the complex endoglycosidase H-resistant form. In these mutations, the receptors remain in the endoplasmic reticulum and are not available on the cell surface. A third type of mutation results in receptors that are expressed on the cell surface, but are unable to bind effectively with LDL-C. A fourth kind of mutation results in receptors that are on the cell surface and can bind with LDL-C but are unable to undergo receptor-mediated endocytosis (99). There is also a less common gain of function mutation in PCSK 9 that results in the rapid disposal of receptors, making them less accessible to bind with LDL-C (100). These mutations all result in the phenotype of elevation of plasma LDL-C.

Genetic abnormalities causing dyslipidemia are important to understand because they increase understanding of underlying mechanisms, and the prevalence for these disorders is relatively high. The prevalence of the homozygous form of familial hypercholesterolemia is 1 in 1,000,000. The prevalence of the heterozygous form of familial hypercholesterolemia is 1 in 500 (101). In some populations, the heterozygous form is as

common as 1 in 300. The heterozygous state is generally fully expressed in the pediatric age range, and it is characterized by total and LDL cholesterol levels of approximately 300 and 240 mg/dL, respectively. These levels may fall somewhat during pubertal maturation. Children and adolescents with the homozygous form of familial hypercholesterolemia have total and LDL cholesterol in the range of 600 to 1,000 mg/dL and 450 to 850 mg/dL, respectively. Homozygous patients develop planar xanthomas (orange-colored skin lesions found on extensor surfaces) by the age of 5 years and develop coronary artery disease between the ages of 10 and 20 years. Patients with homozygous familial hypercholesterolemia often also develop aortic stenosis (102). Patients with the heterozygous form rarely have xanthomas in adolescence. However, they are at risk for coronary artery disease between ages 30 and 50 years. Among individuals who have had a myocardial infarction prior to age 60 years, approximately 5% have the heterozygous form of familial hypercholesterolemia (103).

There are also genetic abnormalities that lead to low HDL-C. These may be due to a primary abnormality in the metabolism of HDL and its major apolipoprotein Apo A-1. This is a heterogeneous group of abnormalities that result in low HDL-C but may or may not lead to premature coronary artery disease (104).

There are also genetic abnormalities that lead to elevation of triglycerides. Familial hypertriglyceridemia is an autosomal dominant disorder but is often not expressed until adulthood (105). The development of obesity, however, can speed its expression. Lipoprotein lipase deficiency is a rare disorder that results in hypertriglyceridemia and can be a cause of pancreatitis and neurologic symptoms (106). The most important aspect of treatment of elevation of triglycerides is very aggressive restriction of dietary fat (107). This is because the level of chylomicrons is very dependent on the intake of total fat in the diet.

Familial combined hyperlipidemia includes the phenotype of elevated plasma LDL-C and triglyceride levels. It has a dominant genetic pattern. It is found in 1% of the adult population and in 10% of survivors of premature coronary artery disease. Children with parents who have familial combined hyperlipidemia may have elevated triglycerides and LDL-C (108). However, the levels of LDL-C are usually lower than in children with heterozygous familial hypercholesterolemia. The specific genetic abnormalities for familial combined hyperlipidemia have not been determined, but it is currently thought to result from multiple genes.

Lipoprotein (a) is a protein that is homologous to plasminogen. It consists of an LDL molecule with its Apo B-100 linked with a disulfide bridge to Apo (a). Higher levels of Lp (a) are associated with increased risk of cardiovascular disease in adults (109). Plasma levels of Lp (a) are inversely associated with the molecular weight of the Apo (a) component (110). Isoforms of Lp (a) are genetically determined. This means that levels of Lp (a) in the plasma are also largely inherited. Generally, levels of Lp (a) >30 mg/dL are associated with increased risk of coronary artery disease and stroke. Because of the homology between Lp (a) and plasminogen, there has been a question of whether increased levels of Lp (a) may also be associated with increased thrombosis. A study in children showed increased risk of thrombosis associated with increased Lp (a) (111). High levels of Lp (a) can be expressed in childhood and adolescence (112).

From a clinical perspective, it is quite difficult to lower LP (a). The only effective pharmacologic treatment is with nicotinic acid, which is difficult for most children and adolescents to tolerate. However, because of the increased risk of atherosclerotic cardiovascular disease associated with increased concentrations of LP (a), it is appropriate to use a more aggressive approach to lower LDL-C, when LP (a) concentrations are elevated.

Diet

Another major factor that influences plasma cholesterol is diet. This has been studied more extensively in adults than in children but seems to have similar effects across ages. The major dietary components that affect plasma cholesterol levels are fat and cholesterol. In particular, it is the amount of saturated fat in the diet that is associated with the level of plasma cholesterol. Saturated fat and cholesterol come primarily from animal-based foods. In addition, there are some plant-based oils that are high in saturated fat, such as palm oil.

It is these relationships that ultimately form the basis for nonpharmacologic treatment of cholesterol elevation. In animal models, those fed with increased levels of saturated fat and cholesterol had increased levels of plasma cholesterol and increased risk of atherosclerosis development (113).

Furthermore, reduction of dietary fat and cholesterol has been shown to result in lower plasma cholesterol concentrations and resolution of atherosclerotic plaque (114).

Secondary Causes of Cholesterol Elevation

There are several secondary causes of dyslipidemia. Selected causes and their underlying mechanisms are presented in Table 71.6. In addition to those listed, liver disease and obstructive jaundice, infection, and obesity are important secondary causes of abnormal cholesterol levels.

Abnormalities of lipids and lipoproteins are seen in both type 1 and type 2 diabetes. When control of diabetes is poor, triglycerides and LDL-C are often increased and HDL-C is decreased. Improved control of diabetes with intensive management of blood glucose can result in improved plasma lipids and lipoproteins (115–117).

Hypothyroidism is associated with increased triglycerides and LDL-C. HDL-C may also be decreased with hypothyroidism. Although it is usually possible to diagnose hypothyroidism by clinical signs and symptoms, occasionally the diagnosis is made because an abnormal fasting lipid profile is found. Appropriate treatment of hypothyroidism results in improvement of abnormal lipids and lipoproteins.

The nephrotic syndrome is a common secondary cause of dyslipidemia in children. Nephrotic syndrome is characterized by proteinuria, hypoalbuminemia, edema, and hypercholesterolemia. Generally, LDL-C is elevated. There may also be hypertriglyceridemia. In this condition, the liver responds to low albumin in the blood by increasing protein synthesis. This includes increased synthesis of the apolipoproteins. This increase in hepatic cholesterol synthesis leads to a down-regulation of LDL receptors in the liver, which in turn leads to a reduced rate of removal of LDL-C from the circulation (118). Usually, the length of exposure to increased LDL-C is short because nephrotic syndrome is easily recognized, is treated, and resolves. This may mean that the impact on the risk of atherosclerosis is low; however, the LDL-C level may be quite high prior to treatment (119).

Patients with chronic renal insufficiency are at high risk for cardiovascular disease (120). The dyslipidemia most commonly seen with chronic renal failure is elevation of triglycerides and a low HDL-C. This may be as prevalent as 30% (121). These abnormalities may contribute to the increased risk of cardiovascular disease seen in patients with chronic renal insufficiency. The hypertriglyceridemia of uremia results from deficiency of lipoprotein lipase or hepatic lipase. Treatment of patients with chronic renal insufficiency should include dietary changes to lower intake of saturated fat, cholesterol, and simple sugars. Increased physical activity may also be helpful in increasing HDL-C.

TABLE 71.6 Selected Secondary Causes of Dyslipoproteinemia

Disease	Elevated Lipoprotein	Mechanism
Type 1 diabetes mellitus	Triglycerides	Defective lipolysis of VLDL owing to inhibition of lipoprotein lipase and hepatic lipase
Type 2 diabetes mellitus	Triglycerides	Overproduction and defective lipolysis of VLDL triglycerides
Hypothyroidism	LDL, triglycerides	Suppression of LDL-receptor activity, overproduction of VLDL
Nephrotic syndrome	LDL, triglycerides	Overproduction of VLDL

VLDL, very low density lipoprotein; LDL, low-density lipoprotein.

Secondary dyslipidemia can result from taking certain medications. For example, estrogen- and progestin-containing contraceptives can result in elevation of triglycerides. Retinoic acid results in elevation of triglycerides in some patients. Anabolic steroids can cause increased LDL-C and lower HDL-C (122).

Acute and chronic infections can result in dyslipidemia. The causative organism and the chronicity of infection determine which lipid or lipoprotein is altered and to what extent (123). Gidding et al. (124) reported that HDL-C and apolipoprotein A-1 were significantly reduced after a recent viral infection in school-aged children. This means that a lipid profile should generally not be measured within 2 weeks of an acute infections.

Metabolic Syndrome

Obesity has been associated with a cluster of risk factors for cardiovascular disease called the metabolic syndrome (73,125). The metabolic syndrome includes increased waist circumference and atherogenic dyslipidemia that consists of elevated triglycerides and low HDL-C. Patients with the metabolic syndrome often also have insulin resistance. This is characterized by high circulating levels of insulin while fasting. There are a number of definitions for use in the clinical setting for diagnosis of the metabolic syndrome in children as well as adults. The prevalence of metabolic syndrome appears to be increasing in children and adolescents as the prevalence and severity of obesity is increasing (126).

The primary clinical approach to treating the metabolic syndrome is improvement in weight through changes in diet and physical activity. It has been shown that with weight management, the components of the metabolic syndrome, including atherogenic dyslipidemia, improve (127).

Clinical Recommendations

Guidelines from the NCEP for Children and Adolescents were first published in 1992 (128). These have been updated since that time, as a substantial amount of research has been done in screening and treatment of dyslipidemia in children (81,129). However, the overall framework presented in the original guidelines remains useful. These guidelines present both a population and an individual approach. The population approach addresses the diet and levels of physical activity that would result

in a healthy lifestyle for all children. The individual approach addresses the recommended guidelines for the identification and treatment of children and adolescents who are at the highest level of risk. This approach provides a more aggressive strategy for changes in diet than the population approach. The individual approach has been updated by the National Heart Lung and Blood Institute in a new set of evidence-based guidelines (81).

Population Approach

The overall goal of this approach is to improve the health of the pediatric population. If the recommended diet was adopted broadly, this would result in a lower prevalence of obesity and a lowering of the population mean for total and LDL cholesterol. It has been suggested by Rose (130) that a small shift in the population mean of a risk factor will result in substantially fewer individuals in the high-risk range. In addition, if lower levels of LDL-C are maintained from childhood into adolescence and adulthood, then it is likely that this would result in lower risk over time for this childhood population.

Diet

The United States Department Agriculture (USDA) guidelines provide diet recommendations for all children (131,132). The proposed diet for young children is somewhat different because infants and young children require a higher level of saturated fat and cholesterol in their diet to support development of the central nervous system. The first 2 years of life is a time when myelination of nerves is occurring. This process requires increased dietary fat intake. However, for children for whom there is a concern about obesity or an increased risk of cardiovascular disease, it is prudent to consider a lower saturated fat diet starting at 12 months of age. This may start with the introduction of lower fat milk at that time (130). This recommendation is supported by the results of the Special Turku Coronary Risk Factors Intervention Project (133). In this randomized controlled clinical trial, children were randomized to either a lower saturated fat diet or a routine higher fat diet at 6 months of age or at weaning. The participants of this study have been followed into their teenage years. There were no adverse effects of the lower saturated fat diet while there were beneficial effects on blood cholesterol (134). For older children, the USDA recommends a diet low in saturated fat and cholesterol (Table 71.7). There is evidence that this type

TABLE 71.7 Population Dietary Recommendations for Children and Adolescents

- Adequate nutrition should be achieved by eating a wide variety of foods low in saturated fat and cholesterol.
- Total caloric intake should be sufficient to support normal growth and development and maintain a desirable body weight.
- Saturated fatty acids should provide <10% of total calories.
- Total fat should provide an average of no >30% and no <20% of total calories.
- Polyunsaturated fatty acids should provide ≤10% of total calories.
- Children should consume <300 mg of cholesterol per day.
- Children should consume ≥5 daily servings of fruits and vegetables.
- Children should consume 6 to 11 daily servings of whole-grain and other grain products.
- Children should consume adequate amounts of dietary fiber (child's age + 5 g/d).

Based on the NCEP, USDA Dietary Guidelines, and The American Heart Recommendations.

Daniels SR, et al. NHLBI guidelines for evaluation, prevention and treatment of atherosclerotic cardiovascular disease in children and adolescents. *Pediatrics* 2011 ;128:S213–S256.

of diet will lower cholesterol levels in children and adolescents without having an adverse effect on growth and development (135,136).

The optimum percentages for dietary intake of macronutrients to reduce LDL-C the most and support normal growth and development are not known. It should also be emphasized that the recommendation of 25% to 30% of calories from fat is not necessarily a daily recommendation but should be a recommendation as an average over several days. This recognizes that daily intake may vary substantially for children based on whether they are in school and where and when they eat (129). Children and adolescents should generally not go below a level of fat intake that is 20% of calories. The purpose of this is to avoid over restriction of fat intake by parents, which could lead to failure to grow and thrive (137).

The population-based diet can also be effective for children with borderline elevation of LDL-C. The population diet can result in a lowering of LDL-C by 3% to 10% (138). Usually, it is necessary for patients to be on the diet for 3 to 6 months to adequately assess its effect.

To achieve the dietary recommendations, 5 to 6 oz/d of lean meats and 24 to 32 oz/d of low-fat dairy products are recommended. Lean cuts of meat include ground or lean meats that have had fat trimmed. Skin should be removed from poultry products. All types of fresh or frozen unbreaded fish are acceptable. Choices for dairy include low-fat or nonfat milk, yogurt, and cottage cheese. Cheeses that contain <6 g of fat/oz (<2 g/oz for the more-restrictive diet with <7% of calories from saturated fat) are acceptable. Eggs should be limited to <2 to 4 per week (131,132).

The largest portion of the child's diet should be made up of whole grains, cereals, fruits, and vegetables. Most of these food choices are high in fiber and low in saturated fat and cholesterol.

One concern with cereals and fruit juices is the intake of increased amounts of simple sugars. This may result in increased levels of plasma triglycerides (139). Other obvious sources of simple sugars are soft drinks and snack foods. Lower-fat and lower-sugar options for snacks include pretzels, graham crackers, and vanilla wafer cookies. Fruit should also be recommended as a healthful snack.

Another issue for the diet of children is the food they eat at school. For those who participate in the school lunch program, it is estimated that nearly 60% of children in the United States eat 25% to 30% of their saturated fat and cholesterol intake at that meal (128). However, schools increasingly offer additional competitive food items as part of their school lunch program. These foods are often higher in fat, saturated fat, cholesterol, and sugar and may be more attractive to children, leading to their increased selection and decreased selection of more nutrient-dense foods.

The population approach to cardiovascular health promotion also includes recommendations for physical activity. Although the optimum level of intensity is not known, increasing the duration and frequency of physical activity and decreasing sedentary time will allow children more flexibility in their diet. For example, the USDA has established recommendations for discretionary calories for children. These are "extra" calories that might be included in the diet once a healthful diet has been consumed and still maintain acceptable energy balance (131,132). The number of discretionary calories increases with age and with the level of physical activity. It is likely that many children are not getting the optimum amount of physical activity and are spending too much time on sedentary pursuits. The American Academy of Pediatrics has recommended no more than 2 h/d be spent on sedentary activities, including television viewing, computer time, and playing video games (140). This means that many children should have only 150 to 300 discretionary calories each day.

One factor that must be considered in implementing the population approach for both diet and physical activity is the role of socioeconomic status (141). Low-income families may have more barriers to purchasing healthful foods. Supermarkets in the inner city may be less convenient and may have lower availability of fresh fruits and vegetables. There are also concerns about neighborhood safety and the lack of opportunities for physical activity including organized sport or unsupervised free-time games.

Implementation of the population-based approach to cholesterol lowering requires the input and cooperation of a number of types of institutions. The government must be involved in improved food labeling and oversight of food assistance programs. Schools must be involved by creating an improved environment for both eating and physical activity. Health professionals should serve as resources for their communities and schools as they develop educational and other risk-reduction programs. In addition, the media can be helpful in the promotion of a healthful diet and increased levels of physical activity.

Individual Approach

The individual approach is directed at identifying children and adolescents who are at higher risk of future cardiovascular disease and treating them to lower their risk. This approach is probably most important from the standpoint of the pediatrician and the pediatric cardiologist. It is this approach that is focused in the physician's office.

Identification

To initiate the individual high-risk strategy, it is necessary to identify those children who are at higher risk of cardiovascular disease. This approach is directed at identifying children who are likely to have genetic dyslipidemias, who are at highest risk.

In adults, the Framingham risk score has been used to stratify risk (125). The use of this score is dependent on all adults having their risk factors including cholesterol measured on a regular basis. These values can then be used in an equation to estimate risk of a cardiovascular event over the next 10 years. Unfortunately, the data are not available to use a similar approach for children and adolescents. To construct a similar risk score for children would require large-scale longitudinal studies with complete follow-up in which risk factor levels are measured in childhood and subjects are followed until the occurrence of cardiovascular end points in adulthood. In fact, it is unlikely that such data will be available. This means that a different strategy will be needed to identify children at high risk.

The NCEP pediatric panel originally recommended a targeted approach to screening using the family history of cardiovascular disease or cholesterol elevation as the indicator for evaluation (128). However, since publication of the original NCEP guidelines, several studies have been performed to evaluate this approach (142–146). In general, these investigations have found that from 35% to 46% of adolescents would have cholesterol measurements based on their family history. These studies have also shown that many children with elevated cholesterol will be missed using a screening approach based on their family history. It is likely that this approach will miss 30% to 60% of pediatric patients with elevated cholesterol (147–149).

Difficulties with using the family history as a trigger for screening include that the family history may be incomplete or inaccurate. The family history would be more useful if all parents and grandparents knew their cholesterol levels, but, unfortunately, this is often not the case. In addition, parents (and sometimes grandparents) of younger children are often too young themselves to have reached the age when they are at greatest risk for a myocardial infarction or a stroke (149).

These problems with a targeted approach to screening have led to the recommendation of universal screening of all children at 9 to 11 years of age (81). In addition, children aged 2 years or older should have a lipid profile if they have a family history of premature cardiovascular disease (prior to age 55 in men or age 65 in women) or of dyslipidemia or with other cardiovascular disease risk factors, such as diabetes, hypertension, or obesity (81).

For universal screening, it is acceptable to use either a fasting lipid profile or a nonfasting non-HDL-C (total cholesterol—HDL-C). If the non-HDL-C is elevated, it should be confirmed with a fasting lipid profile. The focus of universal screening is to identify children with substantial elevation of LDL-C, usually as a result of a genetic dyslipidemia. However, it may also be useful to identify children with elevated triglycerides or a low HDL-C.

The recommended cutpoints for total, LDL, and non-HDL cholesterol are presented in Table 71.8. These cutpoints are used for children and adolescents aged 2 to 18 years. This use across a broad age range is recommended despite the fact that there is considerable variation of cholesterol with age during growth and development. This is especially true during the period of puberty (150–152). Total and LDL cholesterol tend to decline during puberty, meaning that some adolescents will appear normal when, in fact, they will have elevated levels after puberty. However, it has been shown that the proposed single cutpoints work well in practice (153).

The NHLBI has recommended that triglycerides >150 mg/dL and HDL-C <40 mg/dL be considered abnormal for children and adolescents (81).

Use of the Cutpoints

The NHLBI recommends that children and adolescents whose total and LDL cholesterol levels are in the elevated range be considered for treatment (81). Initially, this treatment should focus on improved diet with lower saturated fat and cholesterol. For treatment with pharmacologic agents, they suggest that patients be 8 years of age or older and have even higher levels of LDL-C as would be seen in a genetic form of dyslipidemia. The recommended levels for treatment with pharmacologic agents are presented in Table 71.9. The goal for treatment is to lower the LDL-C to <130 mg/dL, which would be lower than the 95th percentile for pediatric patients.

Treatment

The mainstay of all treatment for dyslipidemia is alteration of lifestyle including diet and the level of physical activity. The initial approach is to use the population-based diet, but to do so more aggressively and with the aid of a dietitian. Dietitians

can be helpful both in providing education about the fat and cholesterol content of foods and in providing behavioral strategies that improve the likelihood that the recommended diet will be adopted by the family and the pediatric patient. Parents can promote improvement in diet by making healthful foods available in the home and restricting the availability of foods that are high in energy density, fat, saturated fat, cholesterol, and simple sugars (154). Research has supported the concept that children will choose to eat foods that are available (155,156). It is important for children to try new foods multiple times to develop familiarity with and ultimately have a preference for these foods. Starting with these foods early in life is also helpful. A minimum of 8 to 10 exposures to new foods may be required before preference for these foods increases and is established (157,158).

For children with greater elevation of LDL-C, a more aggressive approach to diet than the population approach is needed. For these children and adolescents, the NHLBI recommends a diet with <7% of total calories from saturated fat and <200 mg/d of cholesterol. This more-restrictive diet often requires support from a dietitian to accomplish and can result in additional lowering of LDL-C by 4% to 14% (159,160).

Studies have shown that diet therapy is both safe and effective. The Dietary Intervention Study in Children (DISC) is probably the best study regarding this concept. In this investigation, children aged 8 to 10 years with elevated LDL-C were randomly assigned to an intervention group or a usual care group. The intervention group received behavioral intervention focused on adherence to a Step 2 Diet. This involved sessions with the family from 4 to 12 times per year over a 3-year period (161). LDL-C decreased by 15.4 mg/dL in the intervention group and 11.9 mg/dL in the control group. It is encouraging that a 7-year follow-up showed that the intervention effect was maintained and that growth and development continued to be normal in the intervention group (161).

Other studies have supported the results from the DISC study in a clinic setting (162,163). This emphasizes the concept that these changes can be made in practice in a safe and effective manner.

Increasing dietary fiber may also be useful in cholesterol lowering (164). Plant stanol and sterol esters have also been used. These compounds reduce cholesterol absorption from the gastrointestinal tract. Plasma cholesterol reduction of 7% to 15% has been reported using these compounds in a spread (165,166).

Pharmacologic Treatment

There are three main classes of medication used in the treatment of elevated LDL-C in children (167). These are listed in Table 71.10.

TABLE 71.8 Cutpoints for Total and LDL Cholesterol Levels in Children and Adolescents

Category	Percentile	Total Cholesterol (mg/dL)	LDL-C (mg/dL)	Non-HDL-C (mg/dL)
Acceptable	<75th	<170	<110	<120
Borderline	75th–95th	170–199	110–129	120–144
Elevated	>95th	>200	>130	>130

Adapted from Daniels SR, et al. NHLBI guidelines for evaluation, prevention and treatment of atherosclerotic cardiovascular disease in children and adolescents. *Pediatrics* 2011 ;128:S213–S256.

TABLE 71.9 Recommended Values for Pharmacologic Treatment of Children and Adolescents Aged 10 and Older

Patient Characteristics	Recommended Cutpoints
1. No other risk factors for CVD	LDL-C is persistently >190 mg/dL despite diet therapy
2. Other risk factors present including obesity, hypertension, diabetes, cigarette smoking, or positive family history of premature CVD	LDL-C is persistently >160 despite diet therapy

CVD, cardiovascular disease; LDL-C, low-density lipoprotein cholesterol.

Bile Acid Binding Agents. These medications are attractive because they have been available for a long time, are operative in the gastrointestinal tract, and are not absorbed systemically. In addition, their side effects are limited to gastrointestinal discomfort. These side effects can be minimized with increased

intake of water and fiber. Unfortunately, adherence with these medications is often limited because they are difficult for children to take. The powder forms are gritty and must be mixed with juice or water. Even with this mixture, they are difficult to take. The tablet forms are more palatable, but the tablets are

TABLE 71.10 Pharmacologic Intervention for Dyslipidemia in Children

Class	Dose	Side Effects
<i>Bile acid sequestrant</i>		
Colestipol Provided as granules or tablets	1 packet or 1 level scoopful of flavored granules contains 5 g of colestipol hydrochloride. Also comes as tablets; 1–4 tablets/d.	Limited to GI symptoms: constipation, bloating, abdominal cramping. May bind with other medication
Cholestyramine Provided as powder; 1 package contains 4 g	Dose is related not to the weight of the child but to levels of total and LDL cholesterol. Should be started on the lowest dose, 1 package (4 g) and then dosage may be increased over time to daily, 4 packages/d for those most severely affected.	GI symptoms
Colesevelam	Doses of 375-mg capsules/d and 625-mg tablet/d.	GI symptoms
<i>Cholesterol absorption blocker</i>		
Ezetimibe The long-term safety and effectiveness have not been established in children and adolescents	10-mg tablets. The dose recommended is 1 tablet/d.	GI symptoms, liver enzyme elevation, skeletal muscle effects, including myopathy and rhabdomyolysis
<i>HMG-CoA reductase inhibitors</i>		
Atorvastatin	Available in 10-, 20-, 40-, and 80-mg tablets.	Patients on statins should be advised of the risk of myopathy. If muscle pains occur, measurement of CK should be obtained. With increasing doses, liver dysfunction may occur. Measurement of liver function should be obtained prior to drug use and again 6–12 wk after initial therapy or initiation of higher doses and periodically thereafter (e.g., q3mo). May be teratogenic; control advised for use in adolescent females.
Simvastatin The long-term safety and efficacy have not been established in children. In adolescent males, it has been shown to be safe and effective.	Available in 5-, 10-, 20-, 40-, and 80-mg tablets. Dosage is started low and increased as required to lower LDL-C.	

GI, gastrointestinal; LDL, low-density lipoprotein; CK, creatine kinase.

large and difficult for some children to swallow (168–170). If used appropriately, bile acid binding agents can lower LDL-C from 13% to 20% (168–170). The reduction is seen in addition to the cholesterol-lowering effect of diet.

Colesevelam is another medication in the bile acid binding class of medications. The safety and efficacy of colesevelam has been evaluated in a clinical trial of pediatric patients with heterozygous familial hypercholesterolemia (171). They found that colesevelam lowered LDL-C by 6.3% to 12.5% compared to placebo. There were no important adverse effects, and adherence to the medication regimen was good.

Inhibitors of Cholesterol Absorption. Ezetimibe works by blocking cholesterol absorption in the gastrointestinal tract. It is FDA approved for adults, but has not been extensively studied in pediatric patients. Ezetimibe has been shown to reduce LDL-C levels by approximately 20% in adults (172). In adults, ezetimibe is used primarily in combination with statins to achieve additional cholesterol lowering. Because it comes in a single-dose level and because it has so few side effects and is easier to take than bile acid binding agents, it may be attractive as an initial agent for cholesterol lowering in pediatric patients.

HMG-CoA Reductase Inhibitors. HMG-CoA (β -hydroxy- β -methylglutaryl-coenzyme A) medications are usually referred to as statins. These medications competitively inhibit mevalonate synthesis by HMG-CoA reductase. This process is essential for biosynthesis of cholesterol in the liver. In studies of adults, these medications have been shown to be effective in both lowering plasma LDL-C and prevention of cardiovascular end points. This appears to be true of both primary prevention (prevention of an initial myocardial infarction) and secondary prevention (prevention of subsequent myocardial infarctions) (173–175).

A Cochrane review of the use of statins in primary prevention of cardiovascular disease has been published (176). They evaluated 14 randomized controlled clinical trials including more than 34,000 participants. All-cause mortality was reduced by the use of statins, as was combined fatal and nonfatal CVD endpoints, including revascularization. There was no evidence of important adverse events. However, there was some concern about selective reporting of outcomes. There is also some concern about the cost-effectiveness of statins for primary prevention of cardiovascular disease. This may be improved by the availability of cheaper generic forms of statin medication.

Several studies have been performed to evaluate the safety and efficacy of statins in children and adolescents (167,177–183). These studies, although not long-term investigations, have shown effective lowering of LDL-C with minimal side effects and no adverse effect on growth and development.

There have also been studies of statins that have evaluated vascular structure and function as endpoints. De Jongh et al. (181) studied simvastatin and found that after 28 weeks, flow-mediated dilation assessed by vascular ultrasound of the brachial artery was improved to normal levels in patients treated with 40 mg simvastatin compared to no improvement in the placebo group. Wiegman et al. (183) assessed carotid IMT in a clinical trial of pravastatin in children with familial hypercholesterolemia. Participants in the placebo group showed progression of carotid-intima media thickness over 2 years, suggesting progression of atherosclerosis. Those treated with pravastatin demonstrated regression of carotid IMT.

Children and adolescents who are treated with medication for hypercholesterolemia should be started on a low dose of medication with upward titration based on the LDL-C concentrations. Increasing the dose can further lower cholesterol but may also be associated with an increased risk of side effects.

The side effects of statin agents are an increase in hepatic transaminases and elevation of creatine kinase. Statins have also been associated with myositis, which can progress to rhabdomyolysis. If symptoms of abnormal muscle aches or

cramps are present, then creatine kinase should be measured and the medication should be discontinued.

Another concern regarding the use of statins in adolescent females is the potential for these medications to be teratogenic. Women taking statins should use reliable contraception if they are sexually active. Pregnancies should be planned and the medication discontinued prior to pregnancy and through delivery and the duration of breast-feeding. These agents should be used with caution in adolescent females.

A recent meta-analysis of adult patients taking statins has demonstrated a small but measurable increase in risk of type 2 diabetes mellitus in those taking statins, particularly at higher doses (184). While there are potential side effects of statins, they are relatively rare and, on balance, it is clear that the benefits of substantial LDL-C reduction, reduction of inflammation (185), and lowering the risk of adverse cardiovascular disease endpoints outweigh the risks.

Summary

It is clear that cholesterol elevation can contribute to the development of cardiovascular disease owing to atherosclerosis. This means that it is important to identify children and adolescents who are at high risk because of elevated LDL-C. Once such pediatric patients are identified, appropriate dietary treatment should be implemented. When dietary treatment is insufficient, then pharmacologic therapy should be considered in those patients who continue to have substantial elevation of their LDL-C.

HYPERTENSION

Epidemiology

Blood pressure elevation is established as an important risk factor for the development of cardiovascular disease in adults. In the Framingham study, elevated blood pressure is associated with increased incidence of myocardial infarction, cerebrovascular disease, left ventricular hypertrophy, and congestive heart failure (186). A 10-mm Hg increase in systolic blood pressure is associated with a 20% increase in risk of cardiovascular events in adults aged 35 to 64 years (187).

There are numerous potential causes of blood pressure elevation. The most common cause of hypertension in both children and adults is primary hypertension. The mechanism of primary hypertension is not known. It clusters in families, so presumably it has a genetic cause. Primary hypertension may have a heterogeneous cause as some individuals with hypertension have increased sensitivity to salt in the diet, whereas others may have increased activity of the renin-angiotensin-aldosterone system, and still others have increased activity of the sympathetic nervous system. Secondary hypertension is also heterogeneous and may occur as a result of renal parenchymal disease, coarctation of the aorta, renal artery stenosis, and other underlying disease entities.

In adults, it is estimated that 92% to 95% of cases of hypertension are due to essential hypertension (188). Essential hypertension is also the most common form of hypertension in children and adolescents with as many as 90% to 95% of cases without an identifiable cause in primary care clinic-based and population-based studies (189,190).

High blood pressure in children and adolescents is based on percentile values as opposed to a single cutpoint, which is used for adults. For pediatric patients, the 95th percentile based on previous large epidemiologic studies is used to define high blood pressure. For hypertension, the blood pressure must be

elevated persistently over time. The prevalence of hypertension has been previously estimated to be 1% to 3% for children and adolescents (191). More recent estimates have placed the prevalence at approximately 5% (192–194). It appears that average blood pressure may be increasing across the pediatric population over time. Muntner et al. (195) have shown that average blood pressures are higher in more recent national surveys compared with previous surveys. In a multivariable analysis, they also showed that this increase was at least in part owing to population increases in BMI.

Body weight or BMI is the strongest determinant of blood pressure in children. Rosner et al. (196) found that the odds of elevated blood pressure were significantly higher for children in the upper decile compared with the lower decile of BMI. Paradis et al. (197) found that the mean BMI for subjects with elevated systolic blood pressure was 4 to 6 kg/m² higher than in subjects with systolic blood pressure <25th percentile. Sorof et al. (192) found that the strongest determinant of hypertension in a study of school-aged children was BMI. They found that the prevalence of elevated blood pressure after three sequential measurements was 11% for children with BMI > 95th percentile compared with 2% in those with BMI < 5th percentile. These results emphasize that abnormal weight gain and obesity are pivotal factors in blood pressure elevation in children and adolescents (198).

Birth Weight and Blood Pressure

Barker (199) has proposed that birth weight is an important determinant of blood pressure elevation later in life. He hypothesized that infants born with low birth weight owing to fetal undernutrition would have decreased renal mass and changes in vascular structure and function and that these abnormalities would predispose to future hypertension.

Law et al. (200) evaluated this relationship in young adults. They found that lower birth weight and greater weight gain between age 1 and 5 years were correlated with higher blood pressure at age 22. However, not all studies have found this association. Matthes et al. (201) did not find a difference in systolic blood pressure of adolescents with low birth weight compared with those with normal birth weight.

Tracking

In general, there is a continuous rise in blood pressure from infancy through adolescence. However, at any age, there is a wide distribution of blood pressure for both systolic and diastolic blood pressure. The concept of tracking refers to the tendency for individuals to maintain their rank order compared with their peers over time. This means that those with higher blood pressures at one age would also tend to be higher later in life. This would also indicate that those individuals would be at higher risk for cardiovascular disease morbidity and mortality later in life.

Longitudinal studies have shown that blood pressures do tend to track over time for children and adolescents (202,203). Although tracking of blood pressure is reasonably good from an epidemiologic standpoint, there is also substantial variability of blood pressure over time. The prediction of blood pressure at a later age is not as accurate as is the prediction of height from measurements at a younger age (204). However, Cook et al. (205) have shown that the ability to predict future blood pressure level is improved when multiple measurements are taken over several years during childhood.

It has been shown that much of the variability in blood pressure results from variability in weight and BMI, as well as growth (206). In the Muscatine Study, in addition to the current level of blood pressure, changes in weight and adiposity were the most important predictors of future blood pressure (203).

As with cholesterol, the fact that tracking exists for blood pressure over time does not ensure that children who are

destined to have hypertension in adulthood can be readily identified. Results from the Bogalusa study show that of the adults with hypertension, >40% had been in the top 20% in the distribution of blood pressure during childhood (202). Children who maintain a relatively high level of blood pressure over time are, on average, taller, have greater adiposity, and have greater bone age and more advanced pubertal development than their peers (206,207). Data from the Muscatine Study show that of young adults with high systolic blood pressure, 45% had at least one systolic blood pressure measurement in childhood that was >90th percentile and that of adults with elevated diastolic blood pressure, 40% had a diastolic blood pressure elevated during childhood (203).

This raises some question regarding the utility of blood pressure screening in children and adolescents. Wang et al. (208) evaluated the long-term effectiveness and cost-effectiveness of three approaches to managing elevated blood pressure in adolescents. The approaches were (a) no intervention, (b) screen and treat, and (c) population-wide strategies to lower the entire blood pressure distribution. They found that routine screening is moderately effective, but population-based strategies could also be cost-effective for early cardiovascular disease prevention. They recommended that both strategies be implemented in parallel.

Target Organ Effects

Hypertension is associated with increased risk for cardiovascular disease in adults, and treatment of hypertension results in decreased risk over time (209). Elevated blood pressure is also a component of the metabolic syndrome, which is associated with increased risk of cardiovascular disease in adults (73,210). It has been less clear whether hypertension in childhood is related to the development of cardiovascular disease. It has been well known that severe blood pressure elevation, often owing to a secondary cause of hypertension, can result in cerebrovascular disease, hypertensive encephalopathy, congestive heart failure, and even death (195–199). It has been less clear whether milder forms of hypertension including primary hypertension are associated with cardiovascular disease.

The Bogalusa Study and PDAY study have shown that blood pressure elevation is related to the presence of fatty streaks and fibrous plaques in the aorta and coronary arteries (216,217). This means that systemic blood pressure elevation plays an important role in the early stages of the development of atherosclerosis.

Blood pressure elevation has also been associated with increased left ventricular mass in children and adolescents (218–220). This is important because left ventricular hypertrophy has been established as an independent risk factor for cardiovascular disease in adults (221,222). Daniels et al. (218) reported that 55% of pediatric patients with essential hypertension had left ventricular mass index >90th percentile for normal children and 8% had left ventricular mass above the cutpoint of 51 g/m^{2.7} that has been associated with a fourfold increase in adverse cardiovascular events in adults with primary hypertension (222). Studies have used ultrasound to evaluate the carotid artery IMT as a noninvasive surrogate marker of atherosclerosis. Some studies have found an association between blood pressure elevation and increased carotid IMT (223), whereas others have not (224). This is an area that will require further study.

Data are now emerging on the effects of treatment of hypertension on left ventricular mass and other target organ abnormalities. Litwin et al. assessed the effects of 12 months of nonpharmacologic and pharmacologic intervention on left ventricular mass index, left ventricular hypertrophy, and carotid IMT (225). They found that average left ventricular mass index decreased (38.5 ± 10.7 vs. 35.2 ± 7.5 g/m^{2.7}), the prevalence of

left ventricular hypertrophy decreased (46.5% vs. 31.4%), and there was a decrease in carotid IMT (0.44 ± 0.05 vs. 0.42 ± 0.04 mm). All of the results were statistically significant ($p < 0.001$). These are encouraging results that suggest that standard management of hypertension can lead to regression of target organ abnormalities in children with hypertension.

In adults, hypertension is associated with decreased performance on objective physical and cognitive function, even in the absence of subjective symptoms (226). The underlying mechanisms of those relationships have not been clear. Hajjar et al. investigated the association between hypertension and impairment of mobility, cognition, and mood. They also performed brain MRI to evaluate potential abnormalities (227). They found that hypertension increases the risk of concurrent impairments in mobility, cognition, and mood, which were associated with increased disability and mortality. These associations were partly mediated by microvascular injury (white matter hyperintensities) of the brain.

There have also been studies of the potential association between blood pressure elevation and neurocognitive abnormalities in pediatric patients. Lande et al. (228) found that there was an association between elevated blood pressure and decreased cognitive function in school-aged children and adolescents, using data from the NHANES III. Children with elevated systolic blood pressure had lower average scores for digit span, block design, and mathematics compared to children with normal blood pressure. Adams et al. (229) reported that the prevalence of learning disabili-

ties was higher in children with primary hypertension compared to those without hypertension. Lande et al. (230) reported that parental ratings of their child's executive function improved after 12 months of antihypertensive treatment. Taken together, these results emphasize the broad range of target organ abnormalities that can be associated with hypertension in children and adolescents. They also emphasize that treatment of elevated blood pressure can result in improvements in neurocognitive and cardiovascular function.

For most children, blood pressure elevation is not associated with any adverse symptoms. Therefore, most children and their families cannot recognize that blood pressure is elevated. This is why accurately obtained blood pressure measurements are recommended in the clinical setting as part of well child care. This is also why additional testing such as echocardiography is recommended in pediatric patients who are identified with blood pressure elevation, to determine if the blood pressure elevation is having an adverse effect on target organs.

Normal Blood Pressure

Tables for normal blood pressure have been developed from combining data from large epidemiologic studies of blood pressure in children. These values are presented in Tables 71.11 and 71.12. These blood pressures represent values measured in the sitting position using auscultation. It

can be seen from these tables that blood pressure generally increases with age. Blood pressure also increases with height, which is why height percentiles are included in the tables as a way of classifying blood pressure elevation. There is also a strong correlation between BMI and blood pressure. However, this is believed to be a pathologic relationship, so weight or BMI are not considered in determining normal blood pressure, and it is not considered normal for children who are overweight to have higher blood pressure. Separate tables are presented for males and females as blood pressure in males is somewhat higher than for females. This difference by sex increases with age. It has been shown that after accounting for the correlates of blood pressure such as body size, ethnic differences in blood pressure are minimal in childhood and adolescence.

Normal values for blood pressure during the first year of life are presented in Figure 71.4. These values are for the supine position and measured with an oscillometric type of device.

Ambulatory Blood Pressure

Blood pressure has traditionally been measured with the patient resting quietly in a sitting position. This approach to measurement has been very useful both in the research and clinical setting for both children and adults. Nevertheless, it is clear that this does not reflect the variability of blood pressure seen normally during the day and night. Blood pressures measured in the clinic setting may also be subject to the white coat effect. This is a well-recognized circumstance in which

some individuals experience an elevation in blood pressure, not seen in other environments, when they are in the doctor's office.

Ambulatory blood pressure monitoring is a procedure in which a patient wears a portable blood pressure measuring device over a 24-hour period (231,232). This method has been increasingly used in adults and pediatric patients to provide a better characterization of blood pressure. It allows for calculation of mean day and mean night time blood pressure and also the frequency with which blood pressure exceeds the upper limit of normal. Normal standards for ambulatory blood pressures have been published and are available for clinical use (233,234). Ambulatory blood pressure measurements have been shown to be associated with the presence of target organ abnormalities and may be more sensitive than casual blood pressure measurements in indicating risk (231).

Ambulatory blood pressure monitoring is also useful in the evaluation of white coat hypertension. In this case, blood pressure measurements in the clinic setting are persistently elevated, whereas 24-hour ambulatory blood pressure measurements are normal. When white coat hypertension is present, the use of ambulatory monitoring may spare the patient from more intensive treatment. Children with white coat hypertension should not be considered completely normal; however, blood pressure reactivity to stressful stimuli may be a marker for future hypertension (225).

Another aspect of 24-hour ambulatory blood pressure monitoring that may be useful is the normal decline in blood

Figure 71.4. Age-specific percentiles for blood pressure in boys (A) and girls (B) from birth to 12 months of age. BP, blood pressure. (Reproduced with permission from Task Force on Blood Pressure Control in Children. National Heart, Lung, and Blood Institute, Bethesda, Maryland. Report of the Second Task Force on Blood Pressure Control in Children—1987. *Pediatrics* 1987;79:1–25, Copyright © 1987 by the AAP.)

pressure observed at night during sleep. This is often referred to as “dipping” of blood pressure. The normal nocturnal decline in blood pressure is approximately 10%. Nondipping has been associated with higher future blood pressure, increased risk of target organ disease, and some secondary forms of hypertension (236,237).

For pediatric patients with hypertension, 24-hour ambulatory blood pressure monitoring may be useful (232). However, its use requires specialized equipment and trained staff for appropriate application and interpretation of the results.

Definition of Hypertension

In adults, a single set of values is used to define hypertension at any age (209). In children, this would be problematic because blood pressure increases with age as children grow normally. This has led to the definition of hypertension based on percentiles that has been proposed by the National High Blood Pressure Education Program (238). These definitions are presented in Table 71.13. For the diagnosis of hypertension to be established, it is necessary for blood pressure to be elevated (≥ 95 th percentile) on a persistent basis over three separate occasions. The level of blood pressure on the first measurement dictates when the patient should return for repeat blood pressure measurements. Confirming an elevated blood pressure measurement is important because higher blood pressure tends to fall on subsequent visits and may not be persistently elevated. On the other hand, severe blood pressure elevation requires more acute, diagnostic, and therapeutic action.

Measurement of Blood Pressure

For appropriate interpretation of blood pressure, it is important that it be measured appropriately. Unfortunately, in many clinical settings, blood pressure measurements may not be taken at all, and when they are taken, the techniques used may not be appropriate. Even when blood pressure is measured appropriately, it is often not interpreted correctly. Hansen et al. (239) evaluated the frequency of undiagnosed prehypertension and hypertension in a large academic urban medical system with an electronic medical record. They found that prehypertension and hypertension were frequently undiagnosed. This was especially true for younger children without obesity or other cardiovascular risk factors. A greater number

of elevated blood pressures and blood pressure readings in the range of stage 2 hypertension were associated with increased recognition and diagnosis. Training in blood pressure measurement and interpretation for nurses and physicians is often minimal.

Neonates

The optimum method for measurement of blood pressure is the indwelling arterial catheter. In ill neonates, an umbilical artery or radial artery catheter is often in place (240). An alternative method is the oscillometric monitor. These devices have been shown to correlate reasonably well with intra-arterial measurements under controlled circumstances such as during anesthesia (241). However, in the clinical setting, such devices have been shown to vary significantly from auscultation (242). In addition, oscillometric devices may differ from each other (243).

Blood pressures obtained using oscillometric devices are useful when blood pressure is monitored over time and the trend in blood pressure is of particular interest. Blood pressure should be measured in the arm because blood pressure in the leg may be higher than that in the arm (244). Normal standards are not available for blood pressure measured in the leg. Routine blood pressure measurement is not recommended for normal neonates or infants. Blood pressure should be measured in the presence of other medical conditions where hypertension might be expected, such as renal disease or congenital heart disease (Table 71.14).

Older Children and Adolescents

Children aged 3 years and older should have their blood pressure measured in the clinical setting at least annually. It is recommended that blood pressures be obtained with auscultation. The right arm is preferred for blood pressure measurement with the patient seated quietly and the arm at heart level (238). Blood pressure should be measured at all well child and ill visits for children older than age 3 years through adolescence.

The size of the blood pressure cuff bladder is quite important for accurate blood pressure measurement. The use of a blood pressure cuff that is too small will result in a falsely elevated blood pressure recording. The width of the cuff should be at least 40% of the arm circumference at the point midway between the olecranon and the acromion. The length of the bladder should be between 80% and 100% of the circumference of the arm so that it encircles the arm appropriately (245). Therefore, the bladder width-to-length ratio should be

TABLE 71.13 Classification of Hypertension in Children and Adolescents

	SBP or DBP Percentile ^a	Frequency of BP Measurement
Normal	<90th	Recheck at next scheduled physical examination.
Prehypertension	90th to <95th or if BP exceeds 120/80 mm Hg even if below 90th percentile up to <95th percentile ^b	Recheck in 6 mo.
Stage 1 hypertension	95th percentile to the 99th percentile plus 5 mm Hg	Recheck in 1–2 wk or sooner if the patient is symptomatic; if persistently elevated on two additional occasions, evaluate or refer to source of care within 1 mo.
Stage 2 hypertension	>99th percentile plus 5 mm Hg	Evaluate or refer to source of care within 1 wk or immediately if the patient is symptomatic.

^aFor sex, age, and height measured on at least three separate occasions; if systolic and diastolic categories are different, categorize by the higher value.

^bThis occurs typically at 12 years of age for SBP and for DBP.

SBP, systolic blood pressure; DBP, diastolic blood pressure.

TABLE 71.14

Conditions for Which Neonates and Infants Should Have Measurement of Blood Pressure

- Prematurity neonatal complications
- Congenital heart disease
- Renal disease or urologic malformation
- Evidence of elevated intracranial pressure
- Treatment with drugs that raise blood pressure

at least 1:2. In clinical practice, if a cuff is too small, then the next largest should be chosen until the cuff that is the most appropriate size is identified.

The Korotkoff phases are auscultated and used to determine systolic and diastolic blood pressure. The onset of tapping sounds (phase 1) is the point used for systolic blood pressure and the disappearance of sound (phase 5) is used for the diastolic blood pressure. When sounds can be heard to 0 mm Hg, then the onset of the phase 4, or muffing of sound, should be used to determine the diastolic blood pressure.

The mercury sphygmomanometer is the optimum device for measurement of blood pressure. However, because of environmental concerns about mercury, many hospitals have removed mercury manometers from the clinical setting. An appropriate alternative is the aneroid device, which is a mechanical device that is calibrated against the mercury column. In general, automated oscillometric devices are not recommended for routine measurement of blood pressure in children and adolescents. If an automated oscillometric device is used and elevated blood pressure is identified, this should be confirmed using a mercury manometer or aneroid device (238).

Etiology of Hypertension

There is a number of potential causes of hypertension. The likelihood of finding a secondary form of hypertension varies with the age of the child, the degree of blood pressure elevation, and the presence of hypertension in family members. This means that for a younger child, with greater elevation of blood pressure and little or no family history of hypertension, consideration should be given to possible secondary causes. For the adolescent with mild elevation of blood pressure, over-

weight, and a strong family history of hypertension, primary or essential hypertension is most likely.

Neonatal Hypertension

In neonates with blood pressure elevation, an evaluation for secondary causes should usually be performed. The causes of hypertension in the neonate include renal parenchymal disease and renovascular, cardiovascular, endocrine, pharmacologic, and neoplastic disorders. Other causes include bronchopulmonary dysplasia and increased intracranial pressure (246–248).

The evaluation of potential secondary causes in this age group includes measurement of blood pressure in all four extremities to rule out coarctation of the aorta. The history of umbilical artery catheterization may suggest vascular trauma and renal artery stenosis. Usually, a careful history and physical examination will provide clues to the possible cause of hypertension.

For most patients, few laboratory tests are needed. It is important to assess renal function with a blood urea nitrogen (BUN) and creatinine and to evaluate a urine specimen to investigate the presence of renal parenchymal disease.

A chest radiograph and echocardiogram may be useful if signs and symptoms of congestive heart failure are present. Ultrasound of the genitourinary tract is important when renal or urologic abnormalities are suspected. For infants with very high blood pressure for which no cause can be readily identified, an evaluation of possible renal artery stenosis may be indicated.

Children and Adolescents

For older children, the likelihood of secondary hypertension is diminished, but it still may be present. In general, the history and physical examination are most useful in the identification of possible secondary causes. The standard evaluation for children with persistent elevation of blood pressure is presented in Table 71.15. Findings on history that may suggest other causes of hypertension are presented in Table 71.16. Physical examination findings that may suggest secondary forms of blood pressure elevation are presented in Table 71.17. Based on history and physical findings, additional laboratory tests may be performed to evaluate the possibility of an underlying cause for the blood pressure elevation.

Evaluation of Target Organ Abnormalities

Echocardiography is recommended as the main tool for clinical evaluation of target organ abnormalities. Left ventricular mass can be calculated from standard echocardiographic

TABLE 71.15

Standard Clinical Evaluation of Children and Adolescents with Hypertension

Study or Procedure	Purpose
<i>Evaluation for identifiable causes</i>	
History, including sleep history, family history, risk factors, diet, and habits such as smoking and drinking alcohol; physical examination	History and physical examination help focus subsequent evaluation
BUN, creatinine, electrolytes, urinalysis, and urine culture	Rule out renal disease and chronic pyelonephritis
CBC	Rule out anemia, consistent with chronic renal disease
Renal ultrasound	Rule out scar, congenital anomaly, or disparate renal size

BUN, blood urea nitrogen; CBC, complete blood count.

TABLE 71.16 Historical Information that May Suggest Primary or Secondary Hypertension

Information	Relevance
Family history of hypertension, preeclampsia, toxemia, renal disease, tumors	Important in essential hypertension, inherited renal disease, and some endocrine diseases (e.g., familial pheochromocytoma with multiple endocrine adenopathy II)
Neonatal history	Use of umbilical artery catheter suggests need to evaluate renal vasculature and kidneys
Headaches, dizziness, epistaxis, visual problems	Nonspecific symptomatology, usually not etiologically helpful
Abdominal pain, dysuria, frequency, nocturia, enuresis	May suggest underlying renal disease
Joint pains/swelling, facial or peripheral edema	Suggest connective tissue disease and/or other forms of nephritis
Weight loss, failure to gain weight with good appetite, sweating, flushing, fevers, palpitations	In combination, symptoms suggest pheochromocytoma
Muscle cramps, weakness, constipation	May suggest hypokalemia and hyperaldosteronism
Age of onset of menarche, sexual development	May be helpful in suggesting endocrine causes
Ingestion of prescription and over-the-counter drugs, contraceptives, illicit drugs	Drug-induced hypertension

Reproduced with permission from Falkner B, Daniels SR, Flynn JT, et al. The fourth report on the diagnosis, evaluation and treatment of high blood pressure in children and adolescents. *Pediatrics* 2004;114:555–576, Copyright © 2004 by the AAP.

measurements including the left ventricular end-diastolic dimension (LVED), the intraventricular septal thickness (IVS), and the thickness of the left ventricular posterior wall (LVPW). From these measurements, the method of Devereux et al. (249) can be used to calculate left ventricular mass:

LV mass (g) = 0.80

$$\left[1.04 (\text{IVS} + \text{LVED} + \text{LVPW})^3 - (\text{LVED})^3 \right] + 0.6$$

The size of the left ventricle is very dependent on body size and in particular lean body mass (250). This means that the determination of left ventricular mass should be indexed or standardized to allow for comparisons with normal standards. The recommended approach to indexing is to use the height to the power of 2.7. This method comes close to accounting for the patient's lean body mass and excludes any effect that obesity may have on blood pressure. Obesity may have a pathologic effect resulting in elevation of left ventricular mass (251). A conservative cut-point for determining elevation of left ventricular mass index is 51 g/m^{2.7}. This is >99th percentile for normal children and adolescents and is a level that is associated with increased cardiovascular morbidity and mortality in adults with hypertension (222).

Other methods for evaluation of target organ effects such as ultrasound evaluation of the carotid arteries or evaluation of the urine for microalbuminuria are not currently recommended in children and adolescents. Ophthalmologic examination of the retinal vessels may be useful in identifying children and adolescents with retinal vascular changes, which may reflect abnormal changes in other vascular beds.

It is often useful to evaluate children for comorbid conditions that may increase the risk of cardiovascular disease and may be associated with hypertension. This includes a fasting lipid profile and glucose to identify potential metabolic abnormalities that may be part of the metabolic syndrome. In children with a history of snoring, irregular breathing during sleep, and daytime sleepiness, a polysomnogram may be indicated to

evaluate the possibility of obstructive sleep apnea. In the older child and adolescent, a history of alcohol or drug abuse may suggest the utility of a drug screen.

Treatment of Hypertension

An overall approach to the evaluation and treatment of hypertension in children and adolescents recommended by the National Heart Lung and Blood Institute is presented in Figure 71.5A and B.

In general, the initial approach to treatment includes therapeutic changes to lifestyle. If patients are overweight, this should include aggressive weight management. It is when lifestyle changes have been shown to be insufficient and blood pressure remains elevated that more aggressive treatment with pharmacologic agents is instituted.

Lifestyle Modification

There is good evidence in adults that modification of lifestyle focused on changing diet and physical activity can have a beneficial effect on blood pressure. There is increasing evidence that this is true for children as well.

Diet. From the standpoint of diet, overweight, excess intake of salt and alcohol, and low intake of potassium have all been associated with blood pressure elevation (252). However, whether these dietary factors also make good targets for treatment is less clear.

Numerous clinical trials have been conducted to evaluate the relationship of weight loss to blood pressure. Almost all have shown that weight loss or improvement in BMI is related to lower blood pressure in adults. In a meta-analysis, the mean reduction in blood pressure for a weight loss of 5.1 kg was 4.4 mm Hg for systolic blood pressure and 3.6 mm Hg for diastolic blood pressure (253).

In children and adolescents, much of the observed primary hypertension is at least in part related to overweight. With the increasing prevalence and severity of childhood obesity, weight management is an increasing aspect of the nonpharmacologic

TABLE 71.17 Examples of Physical Examination Findings Suggestive of Secondary Hypertension

	Finding	Possible Cause
Vital signs	Tachycardia	Hyperthyroidism, pheochromocytoma, neuroblastoma, primary hypertension
	Decreased lower-extremity pulses; drop in BP from upper to lower extremities	Coarctation of the aorta
Eyes	Retinal changes	Severe hypertension, more likely to be associated with secondary hypertension
Ear, nose, and throat (ENT)	Adenotonsillar hypertrophy	Suggests association with sleep-disordered breathing (sleep apnea), snoring
Height/weight	Growth retardation	Chronic renal failure
	Obesity (high BMI)	Primary hypertension
	Truncal obesity	Cushing syndrome, insulin resistance syndrome
Head and neck	Moon facies	Cushing syndrome
	Elfin facies	Williams syndrome
	Webbed neck	Turner syndrome (coarctation of the aorta)
	Thyromegaly	Hyperthyroidism
Skin	Episodic pallor, flushing, diaphoresis	Pheochromocytoma
	Acne, hirsutism, striae	Cushing syndrome, anabolic steroid abuse
	Café au lait spots	Neurofibromatosis
	Adenoma sebaceum	Tuberous sclerosis
	Malar rash	Systemic lupus erythematosus
	Acanthosis nigricans	Type 2 diabetes
Chest	Widely spaced nipples	Turner syndrome
	Systolic heart murmur	Coarctation of the aorta
	Friction rub	Systemic lupus erythematosus (pericarditis), collagen-vascular disease, end-stage renal disease with uremia
	Apical heave	Left ventricular hypertrophy/chronic hypertension
Abdomen	Mass	Wilms tumor, neuroblastoma, pheochromocytoma
	Epigastric/flank bruit	Renal artery stenosis
	Palpable kidneys	Polycystic kidney disease, hydronephrosis, multicystic-dysplastic kidney
Genitalia	Ambiguous/virilization	Adrenal hyperplasia
Extremities	Joint swelling	Systemic lupus erythematosus, collagen vascular disease
	Muscle weakness	Hyperaldosteronism, Liddle syndrome

BP, blood pressure; BMI, body mass index.

Reproduced with permission from Falkner B, Daniels SR, Flynn JT, et al. The fourth report on the diagnosis, evaluation and treatment of high blood pressure in children and adolescents. *Pediatrics* 2004;114:555–576, Copyright © 2004 by the AAP.

management of hypertension (254). Intervention studies involving weight loss in children with blood pressure elevation have demonstrated beneficial results (255–257). This is also true for clinic-based studies of weight reduction (258). In addition, lipid profiles and insulin sensitivity improve after weight loss (257,258). This means that there is improvement in the main components of the metabolic syndrome. In pediatric studies where an 8% to 10% reduction in BMI is obtained, reduction in blood pressure ranges from 8 to 16 mm Hg (255–258). An important question is whether these benefits are maintained with stabilization of weight. This is an important area

for future research. Because treatment of obesity and maintenance of weight loss are difficult, it is important to focus on prevention of abnormal weight gain in pediatric patients. It is clear that additional increases in BMI through the pediatric age range will have a deleterious effect on future blood pressure no matter what the baseline blood pressure had been (203).

The intake of dietary salt has also been a concern, and reduction of salt intake has been proposed as an important therapeutic modality. Many randomized controlled clinical trials have been performed in adults. In a meta-analysis, a median reduction of urinary sodium of approximately 1.8 g/d

lowered systolic blood pressure by 5.0 mm Hg and diastolic blood pressure by 2.7 mm Hg on average in individuals with hypertension (259). Sodium restriction has also been demonstrated to lower blood pressure when used as an adjunct to antihypertensive medication (260). In addition, sodium restriction can prevent the development of hypertension over time (261). Bibbins-Domingo et al. (262) used the Coronary Heart Disease Policy Model to quantify the potential benefits of population-wide reductions of dietary salt of up to 3 g (1,200 mg of sodium) per day. They found that modest reductions of dietary salt would result in saving 194,000 to 392,000 quality-adjusted life-years and \$10 to \$24 billion in health care costs annually. These reductions are similar to the benefits of reduction in tobacco use, obesity, and cholesterol levels.

One issue that complicates the relationship between dietary salt intake and blood pressure is that the relationship is heterogeneous across individuals. Some individuals appear to be more sensitive to salt in the diet and have a greater increase in blood pressure when exposed to it than others (263). However, this does not appear to be a dichotomous response; instead, it is probably a graded one with varying degrees of sensitivity to salt in the diet (264). In general, the effects of sodium reduction appear to be more pronounced in African American patients (265). Unfortunately, a simple approach to assessment of the degree of sensitivity to sodium is not available for use in the clinical setting.

Infancy may be an important period in relation to dietary sodium. Hofman et al. (266) conducted a randomized trial of sodium reduction in infants. They found a small but statistically significant reduction in blood pressure at 6 months of age. This difference was diminished at 1 year of age after the intervention had ceased. However, a follow-up study was done when the subjects reached age 15. The low-sodium group had significantly lower blood pressure than the normal-sodium group, despite the fact that the intervention had not been continued through childhood (267).

There have been few studies of restriction of dietary sodium in pediatric patients with hypertension (268–271). These studies have yielded conflicting results, with some showing an effect and others showing no effect (267). This may be in part due to the heterogeneity of response to dietary sodium and the inability to identify individuals who are more salt sensitive. It may also be due to difficulty in adherence to a low-salt diet.

Other micronutrients such as potassium and calcium have been studied in children. However, the results of these studies have not demonstrated a strong and consistent enough effect for them to be recommended as targets for therapeutic intervention. Studies have documented a dose-dependent effect of alcohol intake on blood pressure (272). A meta-analysis of studies on adults shows that a median reduction of alcohol consumption of 76% resulted in a reduction in systolic blood pressure by 3.3 mm Hg and diastolic blood pressure by 2.0 mm Hg (273). Although alcohol intake has not been studied extensively in adolescents, it is a potential cause of hypertension. In patients who are identified with alcohol abuse, cessation of intake may provide important improvement in blood pressure.

More recently, studies in adults have focused on dietary patterns rather than specific micronutrients. The best studied diet in adults is the DASH (dietary approaches to stop hypertension) diet. This diet includes increased intake of fruits and vegetables, low-fat dairy products, whole grains, poultry, fish, and nuts. The diet reduces intake of red meat, sweets, and sugar-containing beverages. This diet has been shown to significantly reduce blood pressure in men, women, whites, and African Americans with hypertension (274–277). Of interest is that it has also been shown to reduce blood pressure in adults without hypertension (277). In individuals with hypertension, the diet resulted in a decrease of 11.6 mm Hg for systolic blood pressure and 5.3 mm Hg for diastolic blood pressure.

In adults, the DASH diet has been shown to be safe, effective, and broadly applicable across populations. There have been some studies of the DASH diet in children and adolescents with hypertension. Couch et al. (278) found that the DASH diet resulted in a greater decrease in systolic blood pressure z-scores from baseline to a posttreatment assessment at 3 months compared to hypertensive adolescents who received standard diet restrictions. There was also a trend for a greater reduction in diastolic blood pressure z-scores for the hypertensive adolescents randomly assigned to the DASH diet. The National High Blood Pressure Education Program and the National Heart Lung and Blood Institute(s) have proposed that the use of a DASH eating plan would be appropriate for patients with hypertension in this age range (238).

Physical Activity. Regular physical activity may also be a useful component of therapeutic lifestyle changes to treat hypertension in children. There are many beneficial effects of physical activity including its utility for weight management (278). Whether physical activity has an independent effect on blood pressure is less clear. A meta-analysis of 12 randomized trials in children and adolescents demonstrated that increased physical activity leads to a small reduction in blood pressure (279). However, this decrease in blood pressure was not statistically significant. Nevertheless, it appears that the benefits of increased physical activity and decreased sedentary time outweigh any risks. The National High Blood Pressure Education Program has recommended increased and regular physical activity (30 to 60 min/d of moderate physical activity on most days) as part of the therapeutic lifestyle approach to treatment in children and adolescents (238).

A clinical issue that may arise is the competitive athlete who has hypertension. In general, athletes with mild-to-moderate elevation of blood pressure (prehypertension and stage 1 hypertension) who have no evidence of target organ abnormalities should be allowed to continue in competition (280). It is important for these patients to have ongoing monitoring of their blood pressure (every 1 to 3 months). Athletes with stage 2 hypertension or with evidence of target organ abnormalities should be evaluated more extensively. In these patients, it is prudent to discontinue competitive sports until better control of blood pressure has been achieved.

The role of exercise testing in the evaluation of athletes who have hypertension is controversial. Blood pressures recorded during testing may differ from blood pressures during actual competition (281). In addition, different sports require different amounts of aerobic and isometric activity. In general, resistance exercises such as weight lifting are associated with a higher acute rise in blood pressure during the event. When hypertension and other cardiovascular diseases are present concomitantly, the eligibility for competitive sports will depend on the type and severity of heart disease as well as the level of blood pressure. Careful assessment of the types of activity involved in both conditioning/practice and in competition will allow a more rational decision regarding the level of restriction.

Pharmacologic Treatment of Hypertension

It is well established that treatment of hypertension in adults is associated with a reduction in cardiovascular disease morbidity and mortality (282,283). The evidence base to support pharmacologic treatment of hypertension in children and adolescents is less well developed. However, there have been an increasing number of clinical trials in pediatric patients. These have been primarily short-term studies and have focused on the ability of pharmacologic agents to lower blood pressure as well as the evaluation of safety.

The indications for use of antihypertensive agents are presented in Table 71.18. The decision to use antihypertensive medication is best made on a patient-by-patient basis taking a

TABLE 71.18

Indications for Treatment with Antihypertensive Medications

- Symptomatic hypertension
- Secondary hypertension
- Stage 2 hypertension
- Hypertension (stage 1 or 2) with established target organ damage
- Hypertension (stage 1 or 2) with the presence of other risk factors for cardiovascular disease
- Persistent hypertension (stage 1 or 2) despite implementation of therapeutic lifestyle changes

number of factors into account including clinical features and the acceptance of antihypertensive medication by the family. However, the more severe the blood pressure elevation, the more urgent the use of blood pressure lowering with medication will be.

The therapeutic goal for children and adolescents with hypertension is to lower the blood pressure below the 95th percentile for age and height percentile. However, for some children, such as those with diabetes or chronic renal disease, a more aggressive goal is appropriate. These patients should have blood pressure lowered below the 90th percentile for age, sex, and height as they are thought to be at highest risk for cardiovascular disease over time.

The available medications for routine treatment of hypertension in pediatric patients are listed in Table 71.19. As can

TABLE 71.19

Antihypertensive Drugs for Outpatient Management of Hypertension in Children 1–17 Years Old^a

Class	Drug	Dose ^b	Dosing Interval	Comments ^c
Angiotensin-converting enzyme (ACE) inhibitor	Benazepril	Initial: 0.2 mg/kg/d up to 10 mg/d Maximum: 0.6 mg/kg/d up to 40 mg/d	qd	1. All ACE inhibitors are contraindicated in pregnancy; females of childbearing age should use reliable contraception.
	Captopril	Initial: 0.3–0.5 mg/kg/dose Maximum: 6 mg/kg/d	tid	2. Check serum potassium, creatinine periodically to monitor for hyperkalemia and azotemia.
	Enalapril	Initial: 0.08 mg/kg/d up to 5 mg/d Maximum: 0.6 mg/kg/d up to 40 mg/d	qd–bid	3. Cough and angioedema are reportedly less common with newer members of this class than with captopril.
	Fosinopril	Children >50 kg: Initial: 5–10 mg/d Maximum: 40 mg/d	qd	4. Benazepril, enalapril, and lisinopril labels contain information on the preparation of a suspension; captopril may also be compounded into a suspension.
	Lisinopril	Initial: 0.07 mg/kg/d up to 5 mg/d Maximum: 0.6 mg/kg/d up to 40 mg/d	qd	5. FDA approval for ACE inhibitors with pediatric labeling is limited to children ≥6 y if age and to children with creatinine clearance ≥30 mL/min/1.73 m ² .
	Quinapril	Initial: 5–10 mg/d Maximum: 80 mg/d	qd	
Angiotensin-receptor blocker	Irbesartan	6–12 y: 75–150 mg/d ≥13 y: 150–300 mg/d	qd	1. All ARBs are contraindicated in pregnancy; females of childbearing age should use reliable contraception.
	Losartan	Initial: 0.7 mg/kg/d up to 50 mg/d Maximum: 1.4 mg/kg/d up to 100 mg/d	qd	2. Check serum potassium, creatinine periodically to monitor for hyperkalemia and azotemia. 3. Losartan label contains information on the preparation if a suspension. 4. FDA approval for ARBs is limited to children with creatinine clearance ≥30 mL/min/1.73 m ² .
α- and β-blocker	Labetalol	Initial: 1–3 mg/kg/d Maximum: 10–12 mg/kg/d up to 1,200 mg/d	bid	1. Asthma and overt heart failure are contraindications. 2. Heart rate is dose limiting. 3. May impair athletic performance. 4. Should not be used in insulin-dependent diabetics.

TABLE 71.19

Antihypertensive Drugs for Outpatient Management of Hypertension in Children 1–17 Years Old^a (Continued)

Class	Drug	Dose ^b	Dosing Interval	Comments ^c
β -blocker	Atenolol	Initial: 0.5–1 mg/kg/d Maximum: 2 mg/kg/d up to 100 mg/d	qd–bid	1. Noncardioselective agents (propranolol) are contraindicated in asthma and heart failure.
	Bisoprolol/ HCTZ	Initial: 2.5/6.25 mg/d Maximum: 10/6.25 mg/d	qd	2. Heart rate is dose limiting.
	Metoprolol	Initial: 1–2 mg/kg/d Maximum: 6 mg/kg/d up to 200 mg/d	bid	3. May impair athletic performance.
	Propranolol	Initial: 1–2 mg/kg/d Maximum: 4 mg/kg/d up to 640 mg/d	bid–tid	4. Should not be used in insulin-dependent diabetics. 5. A sustained-release formulation of propranolol is available that is dosed once daily.
Calcium channel blocker	Amlodipine	Children 6–17 y: 2.5–5 mg once daily	qd	1. Amlodipine can be compounded into a stable extemporaneous suspension. 2. May cause tachycardia.
Central α -agonist	Clonidine	Children ≥ 12 y: Initial: 0.2 mg/d Maximum: 2.4 mg/d	bid	1. May cause dry mouth and/or sedation. 2. Transdermal preparation also available. 3. Sudden cessation of therapy can lead to severe rebound hypertension.
Diuretic	HCTZ	Initial: 1 mg/kg/d Maximum: 3 mg/kg/d up to 50 mg/d	qd	1. All patients treated with diuretics should have electrolytes monitored shortly after initiating therapy and periodically thereafter.
	Chlorthalidone	Initial: 0.3 mg/kg/d Maximum: 2 mg/kg/d up to 50 mg/d	qd	2. Useful as add-on therapy in patients being treated with drugs from other drug classes.
	Furosemide	Initial: 0.5–2.0 mg/kg/dose Maximum: 6 mg/kg/d	qd–bid	3. Potassium-sparing diuretics (spironolactone, triamterene, amiloride) may cause severe hyperkalemia, especially if given with ACE inhibitor or ARB.
	Spironolactone	Initial: 1 mg/kg/d Maximum: 3.3 mg/kg/d up to 100 mg/d	qd–bid	4. Furosemide is labeled only for treatment of edema but may be useful as add-on therapy in children with resistance hypertension, particularly in children with renal disease.
	Triamterene	Initial: 1–2 mg/kg/d Maximum: 3–4 mg/kg/d up to 300 mg/d	Bid	5. Chlorthalidone may precipitate azotemia in patients with renal diseases and should be used with caution in those with severe renal impairment.
	Amiloride	Initial: 0.4–0.625 mg/kg/d Maximum: 20 mg/d	qd	
Vasodilator	Hydralazine	Initial: 0.75 mg/kg/d Maximum: 0.75 mg/kg/d	qid	1. Tachycardia and fluid retention can occur. 2. Hydralazine can cause a lupus-like syndrome in slow acetylators.
	Minoxidil	Children < 12 y: Initial: 0.2 mg/kg/d Maximum: 50 mg/kg/d Children ≥ 12 y: Initial: 5 mg/d Maximum: 100 mg/d	qd–tid	3. Prolonged use of minoxidil can cause hypertrichosis. 4. Minoxidil is usually reserved for patients with hypertension resistant to multiple drugs.

^aIncludes drugs with prior pediatric experience or recently completed clinical trials.^bThe maximum recommended adult dose should not be exceeded in routine clinical practice.^cComments apply to all members of each drug class except where otherwise stated.

ACE, angiotensin-converting enzyme; qd, once daily; bid, twice daily; FDA, Federal Drug Administration; ARB, angiotensin-receptor blocker; HCTZ, hydrochlorothiazide; tid, three times daily; qid, four times daily.

be seen, several classes of antihypertensive medications are available for use. In adults, the Antihypertensive and Lipid Lowering Heart Attack Trial (ALLHAT) study compared different classes of antihypertensive medications (285). The results of that study support the preferential use of diuretics and β -adrenergic blockers as first-line agents in the treatment of hypertension. However, subsequent research has called those results into question. Pediatric trials have not focused on comparing different classes of agents in the treatment of hypertension. This means there is little or no evidence base to drive the decision regarding an initial agent in children. However, the choice of certain classes of medication is appropriate for some subsets of patients. For example, angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers are recommended for patients with diabetes or proteinuric renal disease. There is one study that found that these medications can be teratogenic when used in the first trimester of pregnancy (286). A more recent analysis using a large population-based case-control study found that women who reported the use of any antihypertensive medication during pregnancy were at increased risk of having certain cardiovascular malformations. Because the association was not specific for ACE inhibitors or for the first trimester of pregnancy, this suggests the possibility that hypertension itself may be an important factor for congenital abnormalities of the cardiovascular system. In any case, exposure to ACE inhibitors during the second and third trimester is well known to be associated with fetopathy (287). So, the use of these medications in adolescent females should be approached with caution regarding potential pregnancy. Beta-adrenergic blocking agents may be helpful in patients with comorbid migraine headaches.

The approach to treatment in children and adolescents includes starting a low dose of the initial medication. Blood pressure should be monitored and the dose increased until the goal blood pressure is achieved, or intolerable side effects occur. If the first choice of medication is not as effective as desired, a medication from another class may be substituted. Again, the recommended approach is to start with

a low dose and titrate upward until appropriate blood pressure control is achieved. Sometimes it is necessary to add a second agent from another class to the first medication to achieve desired blood pressure lowering. It is useful to consider combining drugs from classes with complementary mechanisms of action (238). In adults, the use of multiple antihypertensive medications to achieve goal blood pressure is increasingly recommended, sometimes even as first-line therapy (288).

In addition to longitudinal follow-up of blood pressure in the clinic, it is important to follow patients for side effects associated with the class of medication being used. It is also important to monitor for target organ changes over time.

Treatment of Severe Hypertension

Severe hypertension may occur in children and adolescents. These patients will have stage 2 hypertension and some may have blood pressure substantially >99th percentile for age, sex, and height percentile. These children frequently have a secondary underlying cause of their hypertension. This is a situation that requires prompt evaluation and treatment. The pharmacologic agents that are useful in the treatment of severe hypertension are presented in Table 71.20. Pediatric patients may also present with hypertensive emergencies. In this situation, the hypertension is often accompanied by hypertensive encephalopathy and possibly seizures. Such emergencies should be treated with an intravenous infusion that can produce a controlled reduction in blood pressure. It is recommended that the blood pressure be lowered by $\leq 25\%$ in the first 8 hours with normalization over a 24- to 48-hour period (289,290).

Hypertensive urgencies occur with less elevation of blood pressure and less serious symptoms, which may include severe headache and vomiting. Children with a hypertensive urgency can be treated with either oral or intravenous antihypertensive agents depending on the level of blood pressure and symptoms present.

TABLE 71.20 Antihypertensive Drugs for Management of Severe Hypertension in Children

Most Useful				
Drug	Class	Recommended Dose	Route	Comments
Esmolol	β -Blocker	100–500 $\mu\text{g/kg/min}$	IV infusion	Very short acting; constant infusion preferred. May cause profound bradycardia. Produced modest reductions in BP in a pediatric clinical trial.
Hydralazine	Vasodilator	0.2–0.6 mg/kg/dose	IV, IM	Should be given q4h when given IV bolus. Recommended dose is lower than FDA label.
Labetalol	α - and β -blocker	Bolus: 0.2–1.0 mg/kg/dose up to 40	IV bolus or infusion	Asthma and overt heart failure are relative contraindications.
Nicardipine	Calcium channel blocker	1–3 $\mu\text{g/kg/min}$	IV infusion	May cause reflex tachycardia.
Sodium nitroprusside	Vasodilator	0.53–10 $\mu\text{g/kg/min}$	IV infusion	Monitor cyanide levels with prolonged (>72 h) use or in renal failure; or coadminister with sodium thiosulfate.

IV, intravenous; BP, blood pressure; IM, intramuscular.

Summary

Hypertension is an important clinical entity in children and adolescents that may be associated with early atherosclerosis and other target organ disease. Recognition of hypertension usually requires blood pressure measurements on a regular basis during well and ill visits. Blood pressure elevation is often accompanied by obesity and other risk factors for cardiovascular disease. Treatment of hypertension requires a stepwise approach, usually starting with therapeutic lifestyle changes and progressing to pharmacologic treatment as needed. For most patients, the goal should be to lower blood pressure below the 95th percentile for age, sex, and height percentile.

HISTORY OF CARDIAC TUMORS

Columbus, a noted pathologist, recorded the first description of a cardiac tumor in 1562 (1). Subsequently, the first report of a cardiac tumor diagnosed in a living patient occurred in 1934, when the presence of myocardial involvement was inferred in a patient with metastatic disease and an abnormal electrocardiogram (ECG) (2). In 1942, surgical resection of two cardiac tumors was reported; both operations culminated in perioperative deaths (3,4). The first successful excision of a cardiac tumor, an atrial myxoma, was performed in 1955 (5).

Despite this rather long history, primary cardiac tumors were, and continue to be, quite rare, especially in the pediatric age group. Their atypical clinical presentation had often prevented timely diagnosis, with discovery at autopsy (6–8). Recent advances in noninvasive diagnosis and surgical management have resulted in marked improvement in recognition, survival, and long-term prognosis.

Most primary cardiac tumors in the pediatric age group are benign. These benign primary cardiac tumors maintain the potential for serious illness related to their conspicuous location. Furthermore, certain primary cardiac tumors can be associated with generalized systemic illness or peripheral emboli. Fewer than 10% of these primary tumors are malignant (6–8). Secondary tumors are also infrequent (7,8). Secondary tumor involvement continues to be quite rare in the pediatric age group although it is encountered more commonly than primary tumors in adults. Secondary tumors usually involve both the myocardium and pericardium. Primary pericardial tumors are also uncommon but again are important because early diagnosis and surgical intervention may be lifesaving.

INCIDENCE

The incidence of cardiac tumors has been difficult to ascertain. Prior data have been limited to autopsy series, case reports, and reviews from large pediatric centers. Based on general autopsy series from patients of all ages, cardiac tumors had a reported incidence from 0.002% to 0.03% (8,9). Autopsy studies in children reported an incidence from 0.027% to 0.08% (6). The earliest reports, with the advent of echocardiography, reported an incidence of primary cardiac tumors of 0.0017% to 0.003%, using the number of hospital admissions as the common denominator (10,11). Using a similar database in a more recent era, 1980 to 1995, the reported incidence of primary cardiac tumors in fetuses to patients 18 years of age evaluated for heart disease at a large pediatric center had increased to 0.2% (12). The incidence of primary cardiac tumors, using the number of echocardiograms at a single pediatric institution from 1981 to 1997 as the denominator, had an incidence of 0.08% (13). In a seven-center collaborative

study of 14,000 fetal echocardiograms, the incidence of primary cardiac tumors was 0.05% (14).

In an attempt to evaluate the incidence of primary cardiac tumors in pediatric patients, a retrospective review was performed between 1980 and 1998 using a computerized cardiology database at Boston Children's Hospital. The incidence was based on a review of all first-time echocardiographic diagnoses of primary cardiac tumors in pediatric patients, which included fetal studies, newborns, infants, children, and adolescents. The denominator of the incidence was all first-time echocardiograms performed during the same time period. The rationale for choosing an echocardiography database implied that most, if not all, pediatric patients with significant murmurs, hemodynamic compromise, dysrhythmias, and associated systemic emboli or unexplained systemic illness seen at Boston Children's Hospital would have undergone echocardiographic evaluation. The computerized pathology registry databases recorded during the same time interval were searched to determine whether any patients had had surgery or whether there had been a sudden death or incidental findings of a primary cardiac tumor that were not included in the echocardiography database. Only one additional patient was found. Hence, using the echocardiography database, 67 primary cardiac tumors were found in review of 38,952 studies, for an incidence of 0.17%. This is similar to the incidence of 0.2% reported in a similar manner during a concurrent time period at the Hospital for Sick Children, Toronto, Ontario (12). The incidence of 0.17% was also similar to 0.14% (14) reported in a multicenter review of fetal echocardiograms. Despite some of the inherent difficulties with these computations, this incidence does present interesting and important new information. The incidence of primary cardiac tumors in the pediatric age group appears to have increased nearly 10-fold. Moreover, this increased incidence is based on echocardiographic recognition of tumors in living patients, not on autopsy findings. This new incidence suggests that one or two new primary cardiac tumors will be detected for every 1,000 first-time pediatric echocardiograms.

Previous autopsy reports have reported that the most common primary cardiac tumors were rhabdomyomas (45%), fibromas (25%), myxomas (10%), intrapericardial teratomas (10%), and hemangiomas (5%) (7,8). The most common tumors in newborns and infants were rhabdomyomas, fibromas, and intrapericardial teratomas. In older children and adolescents, myxomas, rhabdomyomas, and fibromas predominated. Using the recent computerized databases of echocardiography, surgery, pathology, catheterization, magnetic resonance imaging (MRI), and computerized axial tomography, the frequencies of primary cardiac tumors were evaluated at Boston Children's Hospital from 1980 to 2005 (Table 72.1). A total of 129 tumors were found with frequencies as follows: rhabdomyomas (60.5%), myxomas (13.9%), fibromas (7.8%), pericardial teratomas (1.6%), others (7.0%), nonspecified (5.4%), and metastatic dissemination (3.9%)

TABLE 72.1

Frequencies of Cardiac Tumors at Boston Children's Hospital from 1980 to 2005

Tumor	Age at Diagnosis			Total
	<1 Mo	<1 Yr	>1 Yr	
Rhabdomyoma	32	17	29	78 (60.5%)
Myxoma	2	1	15	18 (13.9%)
Fibroma	1	4	5	10 (7.8%)
PT	2	0	0	2 (1.6%)
Other	2	1	6	9 (7.0%)
NS	1	1	5	7 (5.4%)
Mets	0	0	5	5 (3.9%)
Total	40 ^a	24	65	129

PT, pericardial teratoma; NS, not specified; Mets, metastatic cardiac tumor.

^aDiagnosed in utero.

From Steven Colan, M.D., Department of Cardiology, Children's Hospital, Harvard Medical School, unpublished data, with permission.

(Table 72.1). "Others" included three hemangiomas, a mass related to excessive eustachian valve tissue, cardiac calcification, blood cyst of the tricuspid valve, neurofibroma in a patient with neurofibromatosis, hypereosinophilia in a patient with Loeffler syndrome, and one Purkinje cell tumor. Five patients had metastatic tumor dissemination to the heart. Their primary diagnoses included rhabdomyosarcoma, hepatoblastoma, Ewing sarcoma, testicular carcinoma, and malignant melanoma. Three of the five presented with symptoms related to tumor pulmonary emboli. The increased relative incidence of rhabdomyomas seems related to the increased diagnosis of tuberous sclerosis and surveillance echocardiography in patients with known or suspected tuberous sclerosis at a specialized tertiary medical center.

In this Boston Children's hospital experience, in patients diagnosed younger than 1 month of age, (including fetal studies), rhabdomyomas were most often diagnosed (80%), followed by myxomas (5%), pericardial teratomas (5.0%), fibromas (2.5%), others (5.0%), and nonspecified (2.5%) (Table 72.1). All seven of the tumors diagnosed in utero were rhabdomyomas, and six of these patients were subsequently diagnosed with tuberous sclerosis. In a seven-center retrospective review of 14,000 fetal echocardiograms, 19 patients had tumors for a fetal incidence of 0.14% (14). Seventeen of the 19 (89%) were rhabdomyomas and 10 (54%) had tuberous sclerosis. The other tumors included a fibroma and atrial hemangioma. In a similar multicenter retrospective review of patients diagnosed either in utero or at younger than 1 month of age, 84 of 94 patients with cardiac tumors had rhabdomyomas (89%); 80% of these patients had tuberous sclerosis (15).

In patients older than 1 year of age diagnosed at Boston Children's Hospital, rhabdomyomas were diagnosed in 45%, myxomas 23%, fibromas 8%, other 9%, nonspecified 7%, and metastatic dissemination 7% (Table 72.1). The ages of those patients diagnosed with metastatic tumor involvement ranged from 6 to 15 years of age. The median age of presentation for all myxomas was 7 years. The relative increased incidence of myxomas in recent years seems in part attributable to earlier referral and subsequent echocardiographic diagnosis. The increased detection of secondary tumor involvement in the pediatric age group most probably relates to increased awareness and early referral for echocardiographic evaluation.

DIAGNOSTIC PROCEDURES

Electrocardiogram and Chest Roentgenogram

Early studies reported abnormalities on chest roentgenograms in 80% of patients with cardiac tumors (16). Findings including cardiomegaly, abnormal cardiac silhouette, and calcification are nonspecific. Only 47% of patients with primary cardiac tumors have abnormal ECGs. However, in patients with known tumor involvement, the ECG can show S-T segment abnormalities or strain, and ventricular hypertrophy. Additionally, dysrhythmias may be the presenting mode of presentation of cardiac tumors in pediatric patients of all ages. Some have ECG evidence of pre-excitation.

Echocardiography

More than two decades of collective experience have established 2-D Doppler echocardiography as the primary diagnostic procedure for the evaluation of cardiac tumors in pediatric patients (10–43). Two-dimensional Doppler echocardiography is expedient, noninvasive, and accurate. The anatomic and hemodynamic abnormalities can be determined quickly, and critically ill patients can be sent for surgical intervention. More stable patients can be monitored serially by using this noninvasive technique. Echocardiography is also useful for the follow-up of patients after surgical removal of the tumor (44). Two-dimensional echocardiography may aid in tumor differentiation (45,46). Strain and strain rate Doppler tissue imaging has been applied to differentiate tumors based on inherent properties of tissue deformation (47). Transesophageal echocardiography (TEE) provides precise delineation of cardiac tumors and can be used intraoperatively to guide surgical management (48–54). In adults, TEE has been reported to provide improved determination of tumor attachment sites as well as the extent of myocardial/pericardial involvement (54).

Recent developments in matrix array 3-D echocardiography allow timely analysis of tumor volume (Fig. 72.1A–C). The spatial relationship of tumors to other cardiac structures, including atrioventricular and semilunar valves, and inflow

FIGURE 72.1. Three-dimensional echocardiograms using a matrix array transducer. **A:** Large right and left ventricular rhabdomyomas (R) in a newborn. **B:** Round, multilobulated left atrial myxoma (M) in a 2-year-old child. **C:** Large left ventricular fibroma (F) in a 4-year-old boy. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

and outflow tracts can readily be appreciated with 3-D echocardiography (55,56).

Magnetic Resonance Imaging

MRI also shows the location, number, and size of cardiac tumors in the pediatric age group (28,57–72). MRI is also important in the clinical management of secondary tissues because it can visualize mediastinal and other intrathoracic sites (64). Spin-echo MR images provide high-resolution images to enhance delineation of the specific pathology of intracavitary, valvar, myocardial, pericardial, and juxtacardiac masses (Fig. 72.2A). Cine MR provides dynamic imaging techniques to provide additional hemodynamic information (65). MRI can be particularly helpful in visualization of spatial relation of the tumor mass to the coronary arteries, which has been helpful in guiding surgical management. Recent technologic advances in MRI use a combination of sequences that allow differentiation of tumor from myocardium (67) and differentiation of the type of tumor (Fig. 72.2B) (68–72). This MRI technology has been applied to differentiate vascular tumors such as cardiac hemangiomas from rhabdomyomas and fibromas. This differentiation is important in that certain vascular hemangiomas may resolve with either steroid or interferon administration (68,71). In comparative studies, 2-D echocardiography appears to have greater sensitivity than MRI for the detection of intramural (28) and intracavitary cardiac tumors (59); however, MRI has been superior in

detection of apical tumors (59). In a recent multicenter experience of several pediatric centers, 97% of the tumor cases were correctly diagnosed by comprehensive MRI exams (73).

Angiography

Invasive angiography also has been used to diagnose cardiac tumors. This modality provides indirect and nonspecific findings of intracavitary filling defects or cavity obliteration by large intramural tumors. Pressure measurements can be obtained with catheterization, with the inherent risk of placing a catheter near or across a friable tumor. Tissue diagnosis can be attempted by biopsy technique, with the risk of embolizing tumor fragments (43).

RHABDOMYOMAS

Rhabdomyomas constitute 45% to 80% of all primary cardiac tumors in the pediatric age group (7–13) (Table 72.1). They are considered the most common primary cardiac tumor in this age group (7–13). These tumors can be diagnosed in the prenatal period but are most frequently diagnosed in the newborn infant (73–79). Occurrences of sudden death in pediatric patients of all ages, including stillbirths, have been attributed to cardiac rhabdomyomas (74–81).

FIGURE 72.2. A: Spin-echo MRI from a child with a large right ventricular fibroma (F). B: Gadolinium-enhanced MRI, from same child, demonstrating uptake within tumor mass. This uptake indicates fibrous tissue, consistent with a cardiac fibroma. LV, left ventricle; RV, right ventricle. (Courtesy of Tal Geva, M.D., Department of Cardiology, Children's Hospital, Harvard Medical School, Boston, MA.)

In general, rhabdomyomas are multiple, well-circumscribed, noncapsulated, white or gray-white intramural or intracavitary nodules that can occur anywhere within the heart (8,20,21,24,74,77–80), most commonly involving the ventricles (82). Although intramural, these large tumors can encroach on the intracavitary space. Other tumors occur as intracavitary pedunculated masses, or attached by a broad base to the endocardial surface (80–83). Cardiac rhabdomyomas occur as single intramural or intracavitary masses in 10% of patients (8,80,84). Histologically, rhabdomyomas contain large vacuolated cells filled with glycogen (Fig. 72.3). Typical spider cells are seen with eccentric nuclei, granular cytoplasm, and thin

FIGURE 72.3. Rhabdomyoma. Photomicrograph showing cells with clear cytoplasm, vacuolization, and an occasional spider cell (center). (Hematoxylin and eosin stain.) (Courtesy of Peter Paul, MB, BCh, Department of Pathology, Children's Hospital, Harvard Medical School, Boston, MA.)

cytoplasmic extensions projecting toward the cell membrane (80). Rhabdomyomas often are classified as hamartomas, with an inability of cells to undergo mitotic division (80,85).

A rare form of cardiomyopathy, rhabdomyositis, has been described. Tumor nodules are not grossly apparent; microscopically, however, the cardiac muscle fibers and conduction system are diffusely involved with rhabdomyomatous histologic changes (86,87). Recurrent atrial tachycardia and sudden death from intractable ventricular tachycardia have been attributed to rhabdomyositis (86,87).

The clinical findings of cardiac rhabdomyomas are related to the number, position, and size of the tumors. Large intramural or intracavitary rhabdomyomas may obstruct the intracavitary space or the orifice of the atrioventricular or semilunar valves (21,73–77). Extensive cardiac involvement has been associated with diminished myocardial function (18,41,73,77,80). Direct compression of the conduction system can result in serious dysrhythmias (27,37,64,73–84). Rhabdomyomas have been diagnosed by 2-D echocardiography in the fetus (27,75,88–94) (Fig. 72.4). Such prenatal detection has been made while screening fetal dysrhythmias, nonimmune hydrops, decreased fetal growth, and familial tuberous sclerosis (27,75–79,88–94). Postnatally, patients may present without obvious clinical findings, despite extensive cardiac involvement (6,7,40,73,84). Others may have only a murmur of valvular obstructive disease (41,74,77).

Newborns and infants with large rhabdomyomas are often critically ill and present with respiratory distress, congestive heart failure, and low cardiac output (18,73–81). Rhabdomyomas may simulate hypoplastic left heart syndrome when tumors obliterate the left ventricular cavity and severely obstruct blood flow across the mitral or aortic valves (73,95–97). Cardiomyopathy has been diagnosed in newborns and infants with extensive myocardial infiltration (18,41,77). Single pedunculated tumors have been associated with subaortic stenosis (39,41,96–98).

Right atrial or right ventricular rhabdomyomas can cause low cardiac output and signs and symptoms of right-sided

FIGURE 72.4. Two-dimensional fetal echocardiogram at 22 weeks' gestation, demonstrating right and left ventricular rhabdomyomas (R). In utero, a brain MRI scan showed intracranial masses, and at birth the baby was diagnosed as having tuberous sclerosis. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

heart failure (74). Extreme cyanosis can occur when tumors obstruct the tricuspid valve or right ventricular outflow tract, resulting in right-to-left atrial shunting (20,39,41,74,77). Single obstructive pedunculated rhabdomyomas may simulate tricuspid atresia, tetralogy of Fallot, or critical valvar pulmonic stenosis of the newborn (83). The clinical presentation may be even more confusing when rhabdomyomas coexist with significant congenital heart defects (99,100).

Abnormal ECG findings include left-axis deviation, atrial enlargement, ventricular hypertrophy, and ST-T wave abnormalities consistent with ischemia and/or strain (18,73–74,77). These abnormal ECG findings are also indicative of extensive intramural infiltration. Involvement of the conduction system can be inferred from baseline ECGs that manifest bundle branch block (73,74,77), pre-excitation (25,37,39,73,77), or first- through third-degree atrioventricular block (6,22,27,73–75,77,81). Sudden death has been attributed to arrhythmias in pediatric patients of all ages (18,19,27,74–81). These arrhythmias may be a result of either severe hemodynamic compromise or contiguous location of tumors to the conduction

system. All major rhythm disturbances have been reported, including sinus bradycardia, atrial and ventricular tachycardias, and first- through third-degree atrioventricular block. In a more recent large review of 106 patients with rhabdomyomas, 17 (16%) had significant arrhythmias (101). Six percent had ventricular tachycardia and 10% had manifest pre-excitation. In most cases, the rhythm disturbances seemed to resolve with natural tumor regression. When necessary, surgical excision and/or radiofrequency catheter ablation therapy was effective (101).

The chest radiograph may appear normal in older patients with cardiac rhabdomyomas. Occasionally, the only abnormal finding may be distortion of the cardiac silhouette, especially when the rhabdomyomas extend to the epicardium. The chest radiograph, however, often shows cardiomegaly and pulmonary edema in the critically ill neonate and infant (7,18,39,73–77).

The 2-D and 3-D echocardiographic characteristics of cardiac rhabdomyomas are highly echogenic, multiple, well-circumscribed intramural or intracavitary nodules occurring anywhere within the heart (Figs. 72.1A and 72.5) (21,37,40,46,84,87–90,101,102). Rhabdomyomas also may be visualized as either single pedunculated intracavitary or intramural masses (39,40,41,76,84,95,101–103). Rhabdomyomas have a homogeneous, echo-bright, finely speckled pattern (101). In contrast, intracardiac thrombi, myxomas, and hemangiomas have circumscribed echolucent areas as a result of hemorrhage formation. Moreover, rhabdomyomas do not have interspersed, distinct, echogenic regions consistent with calcification or fibrosis. Rhabdomyomas rarely have an associated pericardial effusion (20). Fetal rhabdomyomas are readily diagnosed in utero (Fig. 72.4), and in recent multicenter studies, the in utero incidence of rhabdomyomas was as high as 88% (14) and 89% (15), respectively. Multiple tumors are highly indicative of rhabdomyomas both in the fetus and neonate (14,15,78,79). Fetal rhabdomyomas have been reported to grow in utero ≤ 32 weeks' gestation and then regress in size (79).

Cardiac rhabdomyomas are closely associated with the syndrome of tuberous sclerosis. Tuberous sclerosis is a complex disorder that is transmitted as an autosomal dominant trait of variable expression (104–113). The incidence of tuberous sclerosis has been reported to be 1 in 6,000; two-thirds of cases are sporadic resulting from mutation (79). In an autopsy series, 31% of patients with tuberous sclerosis were reported to have had rhabdomyomas (80). Fifty percent

FIGURE 72.5. Two-dimensional echocardiogram in a newborn infant demonstrating very large right and left ventricular rhabdomyomas (R). The patient was diagnosed with tuberous sclerosis. Despite the large tumors, surgery was not undertaken, and the tumors regressed by 2 years of age. A: Four-chamber view showing extensive right and left ventricular tumors. B: Orthogonal short-axis views demonstrating the extensive tumor mass. Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

of patients with tuberous sclerosis had echocardiographic evidence of tumor involvement (14,84). More recent studies indicate a higher incidence of patients with rhabdomyomas having tuberous sclerosis. Fetal studies indicate that 52% to 79% of all fetuses with cardiac tumors have tuberous sclerosis (14,15,78). The incidence of tuberous sclerosis is as high as 59% to 80% in patients with confirmed fetal rhabdomyomas. Although not invariably, multiple rhabdomyomas are more consistent with the diagnosis of tuberous sclerosis than a singular tumor, with one report indicating that in the fetus or newborn with multiple ventricular tumors, 95% had tuberous sclerosis (15). However, in the latter report, 23% of fetuses or neonates with a singular tumor had tuberous sclerosis as well. In the fetus and neonate, MRI imaging can demonstrate the association of cerebral nodules, establishing the diagnosis of tuberous sclerosis in these patients. The clinical importance of the association between tuberous sclerosis and cardiac rhabdomyomas is evident in a report indicating that 1 in 40 patients with tuberous sclerosis may die as a direct result of cardiac rhabdomyomas (106).

In addition to cardiac involvement, tuberous sclerosis can affect almost all organ systems, including the brain, kidney, pancreas, retina, and skin (104,105,107–109). Therefore, clinical manifestations of tuberous sclerosis may not be clinically apparent in mildly affected patients (107,108,112). Even in severely affected patients, clinical manifestations such as Shagreen patches, adenoma sebaceum, seizures, and mental retardation may not become evident until later in life (105,107–112). Despite the variability in clinical presentation, a family history of tuberous sclerosis or evidence of other organ system involvement may aid in establishing the diagnosis. This is especially germane to the neonate who presents with an intracardiac mass. Neonates with tuberous sclerosis, however, may have no manifestations of this syndrome other than cardiac tumors (77,88,92,93,108). Furthermore, a negative family history does not preclude the diagnosis since $\leq 50\%$ of cases of tuberous sclerosis may be spontaneous mutations. Recent advances in genetic testing may elucidate more fully the inheritance of tuberous sclerosis. To date, two loci associated with tuberous sclerosis have been identified on chromosome 9q34 (TSC1-hamartin gene) and 16p13.3 (TSC2-tuberin gene) (111,112). These loci code for proteins, hamartin and tuberin, that have a tumor-suppressor function (113).

Prostaglandin E_1 (PGE_1), by maintaining patency of the ductus arteriosus, may help stabilize critically ill newborns in whom cardiac rhabdomyomas cause severe right or left ventricular obstruction. Prompt surgical excision is indicated for life-threatening hemodynamic compromise or arrhythmias (37,38,74,77) and is required in $\leq 23\%$ of patient series (95). Partial excision may provide significant relief of inflow or outflow tract obstruction when attempts at complete resection would severely damage the remaining myocardium (18,20,41). The Ross procedure has been proposed when the aortic valve is severely compromised (114). Surgical intervention may be highly successful, without compromising either myocardial or valvular function, in patients with single intracavitary rhabdomyomas (39,83,97,98). Medical treatment has been successful for the treatment of severe dysrhythmias, especially as the tumor resolves. Others have reported successful radiofrequency ablation therapy in select patients with rhabdomyomas and supraventricular tachycardia (115). However, even very large rhabdomyomas may significantly regress in size or disappear completely without intervention (21,37,38,88,98). Unoperated patients may have minimal cardiac signs or symptoms several years later (88). Therefore, the presence of rhabdomyomas alone, without life-threatening hemodynamic instability or arrhythmias, should not be an absolute indication for surgery (17,18,37,38,88,98).

FIBROMAS

Fibromas are generally reported as the second most common primary cardiac tumor in the pediatric age group (1,7,8,12). However, in a more recent review of the Boston Children's Hospital database from 1980 to 2005, fibromas were the third most common tumor (8%) (Table 72.1). Although fibromas have recently been reported in utero (13,14) and in patients younger than 1 month of age (33–36,116–119), they are found much less commonly than rhabdomyomas in this age group. In the recent review at Boston Children's Hospital, fibromas were the second most common tumors (17%) in patients diagnosed between 1 month and 1 year of age (Table 72.1). These primary tumors are rarely seen in older children, adolescents, or young adults. Sudden death has been attributed to cardiac fibromas in pediatric patients of all ages (30,119,120). To date, no distinct genetic inheritance or familial predisposition has been associated with cardiac fibromas. These tumors have been associated with Gorlin syndrome, which includes multiple nevoid basal cell carcinomas, cysts of the jaw, and diffuse skeletal abnormalities (121).

Cardiac fibromas are predominantly single, white, firm, nonencapsulated, intramural tumors that involve the left ventricular free wall or interventricular septum (31,36,116–120,122). These tumors often are located at the left ventricular apex. Less frequently, fibromas can be multiple and invade the right ventricular free wall, atrial septum, or atrial free wall (31,34–36,118,119). Extensive intramural fibromas can encroach and obliterate the intracavitary space (34–36,118,119,122). Although rare, intracavitary fibromas have been reported (34–36,118,119,122), occurring either as a single pedunculated mass (36) or attached by a broad base to the endocardium (33). Both the mitral and tricuspid valve leaflets can be entangled within the tumor mass, causing significant valvar regurgitation (33,34). Similar to rhabdomyomas, fibromas also can be associated with congenital heart defects (89). Cardiac fibromas have been reported to increase in size both prenatally and postnatally (12,13). Histologically, cardiac fibromas consist of fibroblasts, collagen fibers, and minimal elastic tissue (31,32,34,116,119,122) (Fig. 72.6). Occasionally, calcium can be interspersed within the tumor (32,113).

Clinical manifestations of cardiac fibromas are dependent also on the size and location of the tumor. Extremely large

FIGURE 72.6. Fibroma. Photomicrograph showing spindle-shaped fibroblasts and deposition of wavy collagen. (Hematoxylin and eosin stain.) (Courtesy of Peter Faul, MB, BCh, Department of Pathology, Children's Hospital, Harvard Medical School, Boston, MA.)

intramural tumors can encroach the intracavitary space, causing subaortic and subpulmonic obstruction (122). Pedunculated fibromas have been reported to mimic subaortic stenosis (119). Newborns and infants can present with severe congestive heart failure and low cardiac output (33,34,12,123), simulating hypoplastic left heart syndrome (31). Neonates with right-sided fibromas can present with cyanosis and right-sided heart failure, similar to critical pulmonary stenosis or pulmonary atresia (36). Older pediatric patients can have a nonspecific murmur without clinically apparent disease (31,32,76,118,124–126). In this older age group, cardiac fibromas are diagnosed during the evaluation of an incidental abnormality on chest roentgenogram.

As in rhabdomyomas, the ECG is important in the evaluation of pediatric patients with cardiac fibromas. Baseline studies show abnormalities consistent with extensive intramural involvement, including partial to complete bundle branch block and delayed progression of the terminal R wave (118,120,122). The ECG may show QRS axis deviation, atrial enlargement, or ventricular hypertrophy (31–34,116,120,122). Similar to rhabdomyomas, cardiac fibromas invariably have ST-T wave abnormalities consistent with strain or ischemia (31–35,120,122–125,127). These changes have been reported to revert to normal after successful surgery (31,35). Life-threatening arrhythmias can be the primary mode of presentation (31,32,119,123). These arrhythmias include complete atrioventricular block, ventricular tachycardia, and, rarely, supraventricular tachycardia. The diagnosis of a cardiac fibroma often is not established until autopsy, with arrhythmia the presumed cause of death (120). In a recent single institution review of 25 patients with fibromas, 16 (64%) had ventricular tachycardia; two presented with ventricular fibrillation and cardiac arrest (101). Thirteen of sixteen had complete or partial tumor resection and ventricular tachycardia was eliminated in all cases (101).

The chest radiograph may show slight (32,34) or severe cardiomegaly and pulmonary edema (33–36,120–122). Older asymptomatic patients can have nonspecific findings such as an irregular protuberance of the heart border or calcifications within the cardiac silhouette (31,32,35,116,120,125,127).

On 2-D and 3-D echocardiography (Figs. 72.1C and 72.7A,B), cardiac fibromas are seen as a single, bright, intramural, echogenic mass within the interventricular septum or the left ventricular free wall (18,31–33,127). Right ventricular fibromas also have been visualized by this technique (35,36). Multiple fibromas (32,34,119) and calcification within the tumor mass (32,119) have also been reported on pathologic

specimens. Similar to rhabdomyomas, fibromas are rarely associated with significant pericardial effusions. Fibromas may be differentiated from rhabdomyomas by the presence of calcification and cystic degeneration. These tumors may also be differentiated from rhabdomyomas by echocardiographic strain imaging, with fibromas not being compressed during the cardiac cycle (47). These two tumors may also be differentiated by multiple-sequence MRI (68,69) (Fig. 72.2A,B). Fibromas have an inhomogeneous hypointense signal on spin-echo sequences. With gadolinium delayed contrast magnetic resonance angiography, the central signal is again hypointense, with a strong hyperintense shell region (68,69). MRI has also aided in surgical planning to delineate the relationship of the tumor mass to coronary artery anatomy. Fibromas and certain rhabdomyomas may have similar appearances. When surgery is not imminent, complete evaluation for tuberous sclerosis is warranted. Rhabdomyomas may decrease significantly in size or disappear, whereas cardiac fibromas have not been reported to become smaller.

To stabilize the newborn with severe right or left ventricular obstruction, PGE_1 may be used (36). Prompt surgical excision should be undertaken in patients with significant hemodynamic compromise or life-threatening dysrhythmias. Successful removal of large intramural (31,35,36,116,120, 127,124,126–129) and intracavitary pedunculated tumors (117) has been reported in pediatric patients of all ages, with absence of disease reported up to several years later (126–129). In patients with severe tumor involvement, subtotal excision has shown good long tumor survival (128). However, patients with very extensive tumor involvement have undergone cardiac transplantation (129).

MYXOMAS

Myxomas constitute about 50% of primary cardiac tumors in patients of all ages (8,85,130,131). Most often, these tumors are diagnosed in the third to sixth decades of life. Prior autopsy studies in pediatric patients had reported that myxomas constituted 6% of primary cardiac tumors (2). In a more recent echocardiographic-based survey from a single institution from 1981 to 1997, 1 of 22 primary cardiac tumors (4.5%) was a myxoma (17). From 1980 to 1995, 27,640 patients from the fetus to 18 years of age were evaluated at a single center for cardiac disease. Fifty-six patients had a primary tumor; none had a cardiac myxoma (12). This is quite different than the

FIGURE 72.7. Two-dimensional echocardiogram in a 2-year-old child with a large left ventricular fibroma (F). Ao, aorta; LV, left ventricle; RV, right ventricle.

review of the computer database at Boston Children's Hospital, in which 18 of 129 (14%) primary cardiac tumors were myxomas (Table 72.1). In patients older than 1 year, 15 of 65 (23%) primary cardiac tumors were myxomas.

When these tumors occur in neonates and young infants, they often mimic congenital heart disease (132–135). In older children and adolescents, myxomas have manifestations that can lead to severe morbidity and unexpected mortality. Their presentation is often enigmatic because of vague constitutional findings (130,131,136,137). Early diagnosis and prompt surgical intervention can avoid profound illness and death in these patients.

Cardiac myxomas are single left atrial tumors in about 75% and single right atrial tumors in about 25% of patients (124,131,136). Myxomas are generally friable, pedunculated, gelatinous, yellowish brown to red lobular tumors (130,131). These tumors may be calcified (130,131,136,138), with a higher incidence of calcification in right-sided tumors (130,132,133,136,138). The tumor pedicle usually is attached to the fossa ovalis. Rarely, the tumor pedicle is attached to other segments of the atrial septum, atrial free wall, or mitral valve leaflets (131,134,137,139,140). Myxomas can occur as biatrial tumors attached to the fossa ovalis (138,141,142) or as left atrial tumors protruding through the foramen ovale and filling the right atrium (143). These tumors can occur as single right or left ventricular myxomas (130,131,135,144,145) or, infrequently, as multiple myxomas occupying different areas of the same heart (130,136,145).

Histologically, these benign tumors are composed of cords and strands of cells in a pale, paucicellular myxoid background (Fig. 72.8). Multiple small blood vessels, lymphocytes, and histiocytes are seen (130,131). Malignant myxomas are rare and are differentiated by increased mitotic activity and pleomorphism (139,146–148). However, the malignant potential may not be determined by histologic findings alone, (146,147,149). Other characteristics of malignant predisposition include local invasion at the primary site, regrowth of the tumor at the original site or different location, and development of peripheral aneurysms (139,146,147). In $\leq 40\%$ of patients who experience recurrence, the tumor exhibits an abnormal DNA ploidy pattern (150); however, some pathologists doubt the existence of malignant cardiac myxomas (2), suggesting they instead represent misinterpretation of sarcomas (151–154).

FIGURE 72.8. Atrial myxoma. Photomicrograph showing cords and strands of cells in a pale paucicellular myxoid background. (Hematoxylin and eosin stain.) (Courtesy of Peter Faul, MB, BCh, Department of Pathology, Children's Hospital, Harvard Medical School, Boston, MA.)

Myxomas present with a classic triad of symptoms, including cardiac obstruction, emboli, and systemic illness (130,131,136,137,142). Patients are rarely asymptomatic (155,156). The vague and unusual signs and symptoms of cardiac myxomas often have led to delayed diagnosis or misdiagnosis in children and adolescents (137).

About 80% of pediatric patients present with symptoms of valvular obstruction (137). Atrial tumors create mitral or tricuspid valve stenosis by a to-and-fro motion through the valves (130,131). Typically, these large pedunculated tumors advance through and obstruct the atrioventricular valve during diastole and are expelled retrogradely into the atrium during systole. Large left atrial myxomas obstruct pulmonary venous inflow and flow across the mitral valve, resulting in signs and symptoms of pulmonary edema, pulmonary arterial hypertension, and low cardiac output (130,131,155). Ventricular ischemia and dysfunction may develop when cardiac output is significantly impeded (137). Right-sided heart failure and low cardiac output occur when right atrial tumors impede systemic venous inflow and obstruct flow across the tricuspid valve (130–134). Myxomas may mimic neonatal cyanotic heart disease when obstructive right-sided tumors cause right-to-left shunting at the atrial level (132–135). Sudden death has been reported when large tumors completely obstruct either the mitral or tricuspid valve (132,133). Atrial tumors also can cause atrioventricular valve insufficiency (155). Large calcified tumors have been associated with complete valve destruction (136).

Semilunar valve obstruction can occur when large myxomas are inferiorly positioned within the atrium and are attached to a long tumor pedicle (156). This allows atrial tumors to prolapse through the atrioventricular valve and ventricular outflow tract, resulting in diastolic semilunar valve stenosis. Pedunculated ventricular myxomas (157) also can cause systolic aortic or pulmonary outflow tract obstruction (28,135,136,156,158).

Auscultatory findings of left atrial myxomas are consistent with atrioventricular valve stenosis and insufficiency (130, 131,136). A middiastolic murmur and low-pitched tumor plop are characteristic findings (130,131,159); however, absence of the murmur may occur with severe obstruction (119). Right atrial tumors have nonspecific systolic and diastolic murmurs mimicking the Ebstein anomaly or tricuspid valve stenosis and regurgitation (130–134). Symptoms and physical findings are often positional (130,131,136,137). When atrial myxomas obstruct the atrioventricular valves, the patient may experience dyspnea, dizziness, or syncope when sitting or standing, with alleviation of symptoms on lying down. In the neonate, positional symptoms consist of feeding difficulty and irritability while sitting (134). When tumors obstruct the semilunar valves, patients experienced symptoms while bending forward or lying down, with relief of symptoms when standing (157).

Peripheral emboli occur in $>70\%$ of pediatric patients with myxomas (137), including newborns in whom embolization has been reported to have occurred in utero (132). Emboli are related to fragmentation of tumor substance or embolization of thrombi adherent to the tumor external surface (131,160). As expected, left-sided tumors are associated with systemic (161) and right-sided tumors with pulmonary arterial embolization (132,134). Bilateral atrial myxomas have been reported to cause both pulmonary and systemic arterial emboli (142), and right-sided tumors have been associated with paradoxical emboli in patients with atrial septal communications (132,134). Systemic embolization can occlude coronary, pancreatic, thyroid, adrenal, renal, splenic, cerebral, and extremity arteries, resulting in infarction of corresponding tissue (85,142,155,160).

Symptoms related to peripheral emboli may not become apparent until months to years after removal of the primary myxoma (139,142,146,160). This temporal delay has been

attributed to recurrence of nonmalignant myxomas at the same or other cardiac sites (139). The potential for recurrence appears to be associated with inadequate resection (162–165) or totipotent multicentricity (166). Peripheral arterial aneurysms also have been diagnosed years after initial embolic events. Small embolic myxoma fragments may continue to grow, undergo malignant transformation, and invade and replace the medial arterial wall, resulting in aneurysm formation (130,142,146,160).

Constitutional symptoms, the third major component of the clinical triad, occur in $\leq 65\%$ of pediatric patients with myxomas (137). Persistent fever, malaise, weight loss, arthralgias, and myalgias may be present months before tumor diagnosis (130,131,136,137,140,161,167). Laboratory studies show anemia, thrombocytopenia, elevated sedimentation rate, and elevated gamma globulins. Patients have been diagnosed as having acute rheumatic fever, chronic rheumatic carditis, subacute bacterial endocarditis, septicemia, myocarditis, and other collagen vascular disorders (134–140,159,161,167–169). These constitutional findings have been attributed to a diffuse immunologic response to the primary tumor or to tumor emboli (130,134). Recent reports suggested that these systemic abnormalities are secondary to secretion of interleukin-6 and frequently resolve with tumor resection (169–171). Interleukin-6 is associated with the synthesis of several proteins that contribute to the acute-phase response and corresponding constitutional signs and symptoms (172).

Depending on the size and site of the cardiac myxoma, the ECG can demonstrate atrial enlargement or ventricular hypertrophy (130,131,136,137). Right ventricular hypertrophy may be due to pulmonary valvar obstruction, pulmonary arterial hypertension secondary to pulmonary emboli, or pulmonary venous hypertension from left atrial tumors (131). Ischemic ECG changes can occur with tumor embolization to the coronary arteries (160) or with severe obstruction and diminished cardiac output (137,159,160). Bundle branch block, repolarization abnormalities, or severe conduction abnormalities, commonly seen with intramural rhabdomyomas and fibromas, are rarely seen with myxomas.

The chest radiograph may be normal (134,144) or may demonstrate cardiomegaly with pulmonary edema (130,131,134,136). Right-sided myxomas show right atrial and right ventricular enlargement (144,156). Tumor calcification also can be seen (130,131,136). Unlike with rhabdomyomas or fibromas, irregular contour of the heart border is rarely visualized.

The mainstay in the diagnosis of cardiac myxomas is 2-D Doppler echocardiography (130,138,144,156,158,161,173,174). In a retrospective review, myxomas were diagnosed in 37% of patients before, and in 90% of patients after, the advent of echocardiography (175). The virtual pathognomonic finding of an atrial myxoma is that of a large pedunculated tumor mass traversing through the atrioventricular valve in a to-and-fro motion (Figs. 72.1B and 72.9). In some patients, however, the tumor may not appear to prolapse into the ventricle either as a result of a short pedicle or because of its large size (158,173). Single ventricular (158), biatrial (138), and simultaneous atrial and ventricular myxomas (144) have been diagnosed accurately by this technique. Semilunar valve obstruction (135,158) has been corroborated by Doppler technique. Similar to rhabdomyomas and fibromas, pericardial effusions have not been reported with atrial myxomas.

Cardiac myxomas should be removed on diagnosis. Surgical results have been excellent (130,131,136,137), with resolution of associated symptoms (130,136,176). Surgery includes wide resection at the point of attachment of the pedicle to the heart. Since attachment most commonly occurs at the fossa ovalis, removal of large segments of the atrial septum is often done. Careful examination of the entire heart is

FIGURE 72.9. Two-dimensional echocardiogram in a 2-year-old child with a left atrial myxoma (M). LA, left atrium; LV, left ventricle; RV, right ventricle.

necessary to remove concurrent sites of myxomatous tissue. The use of echocardiography to facilitate a surgical approach has been proposed (177) by preoperatively defining tumor size, location, point of attachment, and presence of concurrent site involvement. Patients require continual reevaluation for recurrence of disease and for later development of peripheral arterial aneurysms (130,136,139,142,146,160,175). The approximate incidence of recurrence is 4% to 7% in most large series (162,164,178,179).

Familial occurrence of cardiac myxomas is well established (130,131,136,137,180,181) and accounts for 7% of all myxomas. Cardiac myxomas often are seen in children and adolescents with multiple lentigines syndromes (157) and may be associated with nonneoplastic endocrine abnormalities (Fig. 72.10). Acronyms have been proposed, including LAMB (lentigines, atrial myxoma, mucocutaneous myxoma, and blue nevi) and NAME (nevi, atrial myxoma, myxoid neurofibroma, and ephelides) syndromes. Recent nosology aggregates these conditions under the broader category of Carney complex, which consists of (a) myxomas in other locations (breast or skin), (b) spotty pigmentation (lentigines, pigmented nevi, or both), and (c) endocrine overactivity (pituitary adenoma, primary pigmented nodular adrenocortical disease, or testicular tumors). The precise gene defects remain unknown (182); however, certain investigators have mapped these syndromes to two loci, on chromosome 2p (183) and chromosome 17q (184).

FIGURE 72.10. Facial picture of patient with multiple lentigines.

INTRAPERICARDIAL TERATOMAS

Despite their rare occurrence, intrapericardial teratomas constitute another major subgroup of primary pediatric cardiac tumors (14,73,183) (Table 72.1). These tumors are diagnosed in the fetus or newborn infant. These rare tumors previously were associated with a high mortality rate (185–189). More recently, increased survival is emerging as a result of earlier diagnosis and improvements in surgical care (129,185). Intrapericardial tumors are seldom malignant or recurrent; therefore, surgery is considered curative for such life-threatening illness.

Intrapericardial teratomas are single, encapsulated, grayish tan, bosselated tumors attached to the base of the heart (189–191). These tumors contain multiple cysts within a yellow mucoid stroma (192). Often a broad-based stalk or narrow pedicle firmly attaches the tumor to the root of the aorta or pulmonary artery (185,188,189). The tumor capsule itself can be firmly attached to the aorta (186–200) or to pulmonary artery adventitia (187,189,191,197,200). The tumor has been reported to adjoin the superior vena cava (191), right atrium (187,189,191), right ventricle, left atrium, and left ventricle (189). The tumor blood supply usually emanates as nutrient vessels from the aortic vasa vasorum (187,189,197,198). Single blood vessels from the vicinity of the coronary arteries (190) or multiple small blood vessels from the superior mediastinum also may supply the tumor (191).

Intrapericardial teratomas may be three to four times the size of the newborn or infant heart (186,189,199); however, the tumor may be relatively small in asymptomatic older children and adolescents. Critically ill newborns and babies almost always have a large pericardial effusion (188,189,197). Obstruction and compression of the heart develop due to an essentially solid tumor mass contained within a restrictive fibrous pericardium (188,189,198). In newborns and infants, the tumor is most frequently right sided, attached to the ascending aorta, and wedged between the aorta and superior vena cava (187,188,195–200). These right-sided tumors rotate the heart, on a vertical axis, to the left and posteriorly (189,192,198). They have a propensity to severely obstruct the superior vena cava, pulmonary artery, and ascending aorta. The tumors also may compress the right atrium and right ventricle (186–189,200–203). Less frequently, the tumor is left-sided, attached to the aorta, overlying the left atrium and left ventricle (189,192,198). Left-sided intrapericardial teratomas rotate the heart anteriorly and to the right (189,192,198). Rarely, the tumor is located posteriorly behind the aorta (192). Intrapericardial teratomas also can occur concomitantly with other congenital heart defects (189,190).

Intracardiac teratomas occur even less frequently than intrapericardial teratomas (201). To date, they have been found predominantly on the right side of the heart. These intracardiac teratomas cause findings similar to those for the intramural and intracavitary tumors described above. Intracardiac teratomas are rarely malignant in young infants and children (201,202).

Intrapericardial teratomas consist of tissue derived from all three embryonic germinal layers (Fig. 72.11) (185–199). Mesodermal tissue includes smooth and striated muscle, hyaline, and elastic cartilage. Endodermal tissue consists of respiratory bronchial, pancreatic, intestinal, and salivary glands; ectodermal neuroepithelial structures include choroid plexus and eyes. Intrapericardial teratomas are rarely malignant, particularly in infants and newborns (185,188,192,195).

Intrapericardial bronchogenic cysts have the same gross appearance and clinical manifestations as intrapericardial teratomas (187,192,194,195,199). These two intrapericardial tumors can be differentiated only by histologic examination. Intrapericardial bronchogenic cysts consist predominantly of

FIGURE 72.11. Photomicrograph of pericardial teratoma showing primitive neural tissue including ependymal type rosette (left aspect of photograph) and immature glands and stroma, with foci of endodermal sinus tumor. (Hematoxylin and eosin stain.) (Courtesy of Harry Kozakewich, M.D., Department of Pathology, Children's Hospital, Harvard Medical School, Boston, MA.)

respiratory and gastrointestinal tissue. They do not have the neuronal tissue elements that can be found in intrapericardial teratomas (187,192,194). The true incidence of intrapericardial teratomas remains somewhat unclear because earlier reports may have included intrapericardial bronchogenic cysts (187,192).

Half of all intrapericardial teratomas are diagnosed in newborns and infants younger than 1 month of age and two-thirds in infants younger than 1 year of age (192,198). In recent reviews from Boston Children's Hospital (Table 72.1) and other centers (13,14), all intrapericardial teratomas were diagnosed in infants younger than 1 year of age. Critically ill newborns and infants have a distinct clinical presentation consisting of respiratory distress, pericardial effusion, and direct cardiac compression by the tumor mass as well as cardiac tamponade (185–199). Nonimmune fetal hydrops has been attributed to intrapericardial teratomas (186). Direct compression of pulmonary parenchyma may contribute to the extreme respiratory distress in the newborn or infant (187,191,198,199). Sudden deaths occurred in two-thirds of pediatric patients who had intrapericardial teratomas (188). These events were attributed to acute rupture of cysts into the pericardial space with sudden tamponade (203), severe encroachment by the tumor on the heart and great vessels (188,191), and infectious pericarditis (191).

Signs and symptoms of severe disease may not be apparent in the rare situation in which an infant does not have an associated significant pericardial effusion (189,192,198). Patients older than 3 months of age are usually asymptomatic or have findings of a chronic pericardial effusion (189,192,198). Intrapericardial teratomas can be diagnosed in the asymptomatic older child during evaluation of an abnormal chest radiograph or as an incidental finding at autopsy (189,192,198).

Heart sounds are distant or muffled, murmurs are inaudible, and the precordial impulse conspicuous for its absence in the newborn or infant who has impending tamponade (185,189,192,196,199). The patient may have marked hepatomegaly and diminished peripheral pulses (185,192,198). Stenotic murmurs may be heard when the tumor mass compresses cardiac chambers or great vessels (195,198). The newborn may present with cyanosis from compression of the

FIGURE 72.12. Fetal echocardiogram showing massive heterogeneous intrapericardial mass attached to the right atrium and aorta. Histology confirmed this mass to be a pericardial teratoma (PT) (see Fig. 72.11). LV, left ventricle; RV, right ventricle; SP, spine.

pulmonary parenchyma (185,199) or from right-to-left atrial shunting (195).

Low-voltage QRS complexes are often seen (185,186, 189,192,198). Arrhythmias, ST-T wave abnormalities, and intraventricular conduction delays are notably absent. In critically ill patients, a markedly enlarged cardiac silhouette is seen on chest radiographs (185–199). Calcifications may also be visualized on radiographic studies (189,199,200). Irregularity of the cardiac silhouette may be the only abnormal finding in older asymptomatic patients (192).

Pericardiocentesis is nondiagnostic except for the absence of a bloody effusion (189). A hemorrhagic effusion almost always is associated with a malignant cardiac or pericardial tumor (189). Recurrence of the pericardial effusion invariably occurs if the tumor is not removed (189,191).

Intrapericardial teratomas have been visualized by 2-D echocardiography in the fetus, neonate, and infant (13,185–187,192,193,196–198,200) (Figs. 72.12 and 72.13). The tumor appears as a single, nonhomogeneous, lobular, intrapericardial mass (Fig. 72.11) (185,187,191,196–198,200). Pericardial effusion is almost always present in the neonate

and infant. Cystic formations appear as echolucent areas, calcifications as echogenic foci (185,187,196). Attachment of the pedicle to the aorta can be visualized, and compression of the great vessels and intracardiac chambers may occur (187,193,196–200). Neonates and infants have been operated on the basis of echocardiography alone (185,187, 196,202). MRI has been applied to the differentiation of intrapericardial teratomas from bronchogenic cysts (201).

Early noninvasive diagnosis, surgical removal of the intrapericardial teratoma, and decompression of the pericardial effusion result in high survival rates, even in critically ill neonates and infants. In utero recognition allows prompt postnatal surgical intervention before significant cardiopulmonary distress develops (197). Surgery in older asymptomatic patients is indicated because of the propensity of these tumors to cause sudden death (185,187–189,191,195) or to undergo rare but known malignant degeneration (185,198). Careful dissection is necessary to remove a tumor that is adherent to the external surface of the heart or coronary arteries (187,189,191) and to remove the tumor pedicle from the aorta or pulmonary artery (187,191,192,198,199). Successful long-term results have been reported following surgery (129,185–187,192,198,199).

OTHER PRIMARY BENIGN MYOCARDIAL TUMORS

Cardiac hemangiomas are another more common benign tumor in this age group (7,204–206). In the review of 129 primary cardiac tumors at Boston Children's Hospital, three (2.3%) were hemangiomas. These tumors are almost always single and can occupy the epicardial, intramural, or intracavitary space (206). Hemangiomas are polypoid or sessile, often with central areas of necrosis and calcification (17,62,205). They often are associated with nonhemorrhagic pericardial effusions. These tumors consist of large blood vessels and small vascular channels interdigitating within the myocardium (17,205). On echocardiography, these vascular channels appear as large echolucent areas (17,204,205). Angiography has been used to demonstrate the highly vascular nature of these tumors (17,62,204). Recently, MRI has also been used to differentiate the highly vascular nature of cardiac vascular tumors (68,70,71), particularly with rapid enhancement on first-pass gadolinium scanning. The importance of

FIGURE 72.13. Huge intrapericardial teratoma (P) in a newborn infant. A: Four-chamber view showing the heterogeneous mass with multiple vacuoles at the region of the right atrium, within the pericardial space. B: Orthogonal short-axis views showing the large tumor mass in the pericardium. LA, left atrium; LV, left ventricle; PT, pericardial teratoma; RV, right ventricle.

tissue differentiation has been emphasized in that congenital hemangiomas may regress in size with interferon or steroid administration (71). The variability in clinical course may be related to the variability in histology (71). Some patients have been reported as being well 4 years following diagnosis (204). Sudden death has also been reported (1,85,206). Surgical intervention has been successful in removal of singular intracavitary tumors (17,204,205). Cardiac transplantation has been considered in some patients who had severe invasion of the myocardium (17).

Other examples of rare primary benign cardiac tumors include papillary tumors (207), accessory endocardial cushion tissue (208), cardiac lipomas (72,209–211), and fibroelastomas (212). These tumors have been associated with a myriad of cardiac signs and symptoms ranging from minimal disease to systemic embolization to near-death episodes. MRI has been able to differentiate cardiac lipomas from other tumor masses (68,72).

PRIMARY MALIGNANT MYOCARDIAL TUMORS

Malignant myocardial tumors constitute <10% of primary cardiac tumors in pediatric patients (7,8,63). These malignant tumors include fibrosarcoma, angiosarcoma, lymphosarcoma, giant cell sarcoma, fibromyxosarcoma, leiomyosarcoma, neurogenic sarcoma, rhabdomyosarcoma, and undifferentiated sarcoma (43). Some pathologists argue that the imprecise terminology applied to these tumors has been a general source of confusion (148). Moreover, the histologic differentiation of benign from malignant tumors may be subtle (146).

Angiosarcoma is the most frequent primary malignant cardiac tumor (213–216). These tumors most often involve the right atrium and pericardium. Patients present with cardiac tamponade, right-sided heart failure, and superior vena caval obstruction. Pericardial effusions are hemorrhagic; metastatic involvement of the liver, lungs, and central nervous system is common. Despite early noninvasive diagnosis and surgical and chemotherapeutic interventions, the outlook remains poor.

Cardiac sarcomas are rare in patients of all ages. In a National Sarcoma Registry database, 0.4% were thoracic sarcomas, with only one case of cardiac sarcoma reported (217). Although rare in pediatrics, primary cardiac sarcomas have been diagnosed in infants as young as 3 months of age (43). These tumors usually involve the right side of the heart (43,218–221) and often are located primarily in the pulmonary artery (219). Poorly differentiated sarcomas can infiltrate the right atrium and right ventricle, extend to the pericardium, and encroach on the atrial and ventricular cavities (43). Surgical removal of these tumors has been attempted (43,219) with a low survival rate and with both local and distant recurrence (43,219,222). Often, the tumor is so invasive that surgical removal is impossible. Metastases to the lung and mediastinum often occur, and prognosis is poor (43,218,219). Certain nonresectable sarcomas, without evidence of distant metastasis, have been approached by cardiac transplantation (222–230). The role of transplantation in the management of such patients is unclear.

SECONDARY CARDIAC TUMORS

Secondary cardiac tumors more frequently are observed than primary tumors. The most common secondary tumors in pediatric patients are non-Hodgkin lymphoma, leukemia, and neuroblastoma (7,63).

Non-Hodgkin lymphoma is becoming more prevalent, with occurrence seen in immunosuppressed patients who are infected with Epstein-Barr virus (231). Occurrence is 0.2% and 1.2% in the 1st year in renal and cardiac transplant recipients, respectively, with rates of 0.04% and 0.30% per year, respectively, for kidney and cardiac transplant patients thereafter (232). In the cardiac transplant patients who develop non-Hodgkin lymphoma, the incidence of direct cardiac involvement is 18% (233). Cardiac involvement from non-Hodgkin lymphoma can present with pericardial effusions, arrhythmias, and congestive heart failure (234,235). Marked ST-T wave abnormalities, low-voltage QRS complexes, and infarct patterns are seen (234,235). Two-dimensional echocardiography shows significant ventricular wall thickening and dyskinesis (234). The myocardium has echo-bright areas alternating with echolucent areas. This is consistent with autopsy findings of large areas of necrosis and hemorrhage alternating with myocardium and solid tumor (234,235).

Direct extension from the inferior vena cava to the right atrium can occur in patients with Wilms tumor, renal myosarcoma, leiomyoma, and leiomyosarcoma (236–239). Patients with Wilms tumor can have symptoms of right heart obstruction or failure before presenting signs and symptoms of an abdominal mass or hematuria (238). Ultrasound can demonstrate a tumor extending proximal to the iliac arteries, continuing up the inferior vena cava to the right atrium (237,238). Large atrial tumors can prolapse into the left atrium through an atrial septal communication (239). Atrial Wilms tumors can mimic atrial myxomas by their to-and-fro motion across atrioventricular valves (239).

Malignant pericardial tumors are usually metastatic (8,85,157). Rarely, primary intrapericardial tumors do occur (235). Metastatic tumors directly invade the pericardium and often are associated with hemorrhagic effusions. These tumors can invade the myocardium but rarely invade the intracavitary space (235).

Robert E. Shaddy ■ Lloyd Y. Tani

Hear failure in children is a very heterogeneous syndrome with multiple possible causes and treatments. This chapter reviews the causes of heart failure in children and discusses the management of chronic heart failure. Acute heart failure is addressed elsewhere in this book.

ETIOLOGY OF CHRONIC HEART FAILURE IN CHILDREN

Accurate determination of the cause of heart failure in children is critical to both prognosis and optimal treatment. In children, it is useful to consider the various causes of heart failure by age. Although not absolute, this classification provides a useful framework from which to approach children with suspected or known heart failure. In the following discussion, causes are considered in two broad age categories: (a) neonates and infants and (b) children and adolescents (Table 73.1). Most of the entities included in this section are discussed in greater detail elsewhere in this textbook. Causes of heart failure in the fetus include structural heart disease, arrhythmias, and myocardial dysfunction, and are discussed in Chapter 27 (Fetal Echocardiography and Fetal Cardiology).

NEONATES AND INFANTS

Heart failure in neonates and infants can occur due to a variety of causes including structural heart disease, myocardial dysfunction, arrhythmias, and metabolic abnormalities. Congenital structural anomalies can be broadly classified as volume overload lesions, pressure overload lesions, and complex lesions that often involve a combination of pressure and volume overload.

Heart failure that presents at birth may be due to asphyxia-related myocardial dysfunction, hypoglycemia or hypocalcemia, sepsis, anemia or polycythemia, myocarditis, arrhythmias (supraventricular tachycardia, congenital complete heart block), a sizable atrioventricular malformation, or severe tricuspid regurgitation (asphyxia-related papillary muscle dysfunction, Ebstein anomaly, tricuspid valve dysplasia) (1).

Pressure overload lesions presenting in neonates include left heart obstructive lesions such as critical aortic valve stenosis, coarctation of the aorta or interrupted aortic arch, and the spectrum of left heart hypoplasia. Neonates with these anomalies depend on the ductus arteriosus to provide systemic blood flow and typically present between 2 days and 2 weeks of age, coincident with ductal constriction and closure. The combination of compromised cardiac output and ventricular dysfunction results in tachypnea, poor pulses, poor perfusion,

pallor, feeding difficulty, and sometimes circulatory collapse and shock.

Many volume overload lesions present in infancy and include significant left-to-right shunts (ventricular septal defect, atrioventricular septal defect, patent ductus arteriosus, truncus arteriosus, aortopulmonary window, forms of single ventricle without obstruction to pulmonary flow, pulmonary atresia with ventricular septal defect and large aortopulmonary collaterals, and total anomalous pulmonary venous return without obstruction). In such cases, pulmonary flow increases as pulmonary vascular resistance drops, resulting in pulmonary overcirculation and, in some cases, decreased systemic blood flow (2). An additional factor contributing to the increasing left-to-right shunt in this age group is the physiologic fall in hemoglobin (3).

Complex structural anomalies may combine pressure and volume overload, in some cases resulting in a combination of heart failure and cyanosis. Detailed descriptions of the anatomic subtypes with their physiologic and hemodynamic consequences are presented in other chapters. Broadly, this group of lesions includes variable combinations of ventricular hypoplasia (including functionally single left or right ventricles), atrioventricular valve dysfunction, critical obstruction to systemic flow, obstruction to pulmonary venous drainage or systemic ventricular inflow, and intracardiac shunting. As neonatal cardiac surgery has evolved, more neonates, infants, and young children who have undergone palliative or corrective cardiac surgery are at risk for heart failure owing to residual abnormalities including residual shunts, systemic outflow tract obstruction, myocardial dysfunction, significant semilunar or atrioventricular valve regurgitation, pulmonary venous or systemic ventricular inflow obstruction, and/or rhythm disturbances.

Ventricular dysfunction in young children can occur due to a number of causes. A relatively uncommon form of congenital heart disease that presents at 1 to 2 months of age is anomalous origin of the left coronary artery from the pulmonary artery (4,5). As pulmonary vascular resistance drops, antegrade perfusion of the left coronary artery from the pulmonary artery also drops, resulting in myocardial ischemia and dysfunction. Babies with this anomaly present with fussiness, irritability, poor feeding, including crying and pallor after eating (angina), tachypnea, diaphoresis, and, in some cases, cardiovascular shock. Although uncommon, this diagnosis must be considered in any infant presenting with left ventricular dysfunction and heart failure (6,7). Ventricular dysfunction occurring in the setting of myocarditis or related to various forms of cardiomyopathy (CM) (dilated, hypertrophic, or restrictive) may present with heart failure in this time period (7–10). Sustained supraventricular tachycardia may result in acquired ventricular dysfunction and heart failure (11,12). Noncardiac causes such as renal failure or sepsis may also result in low cardiac output and heart failure (1). These entities are described in detail in other chapters.

TABLE 73.1 Etiology of Chronic Heart Failure**Neonates and infants**

- Structural heart disease
 - Pressure overload
 - Severe/critical aortic stenosis
 - Aortic arch obstruction (coarctation or interruption)
 - Volume overload
 - Left-to-right shunt
 - Ventricular septal defect
 - Atrioventricular septal defect
 - Patent ductus arteriosus
 - Truncus arteriosus
 - Aortopulmonary window
 - Large aortopulmonary collaterals
- Valvular dysfunction
 - Atrioventricular valve insufficiency (post-op atrioventricular canal, Ebstein anomaly)
 - Semilunar valve insufficiency
 - Aortic insufficiency after valvotomy
 - Truncal valve regurgitation
 - Tetralogy with absent pulmonary valve
- Complex
 - Single ventricle (obstruction to systemic ventricular outflow, obstruction to ventricular inflow or pulmonary venous return)
- Myocardial dysfunction
 - Ischemia
 - Anomalous left coronary artery from the pulmonary artery
 - Asphyxia-related ventricular dysfunction
- Cardiomyopathy
 - Myocarditis
 - Primary
 - Secondary (arrhythmia, renal, hypothyroid, hypoglycemia, sepsis, etc.)
- Postoperative ventricular dysfunction

Children and adolescents

- Unoperated structural heart disease

- Left heart failure
 - Increase in mitral regurgitation
 - Increase in aortic regurgitation
 - Progressive aortic outflow obstruction
- Right heart failure
 - Ebstein anomaly
 - Eisenmenger syndrome
- Rhythm disturbances
- Postoperative structural heart disease
 - Left heart failure
 - Myocardial dysfunction (ischemia, fibrosis, systemic single or right ventricle)
 - Volume overload (residual shunt, valve regurgitation)
 - Pressure overload (residual and/or progressive aortic outflow obstruction)
 - Right heart failure
 - Ventricular dysfunction
 - Pressure overload (residual outflow obstruction, pulmonary hypertension)
 - Volume overload (pulmonary or tricuspid insufficiency)
 - Rhythm disturbances
- Structurally normal heart
 - Cardiomyopathy (primary)
 - Dilated
 - Hypertrophic
 - Restrictive
 - Cardiomyopathy (secondary)
 - Infectious or inflammatory (myocarditis, endocarditis)
 - Ischemia (Kawasaki disease, other forms of coronary artery disease)
 - Chronic volume overload (acquired valve dysfunction, rheumatic heart disease)
 - Chronic arrhythmia
 - Toxins (anthracyclines, radiation)
 - Muscular dystrophy
 - Metabolic

CHILDHOOD OR ADOLESCENCE**Unoperated Structural Heart Disease**

Although presentation with heart failure because of unoperated congenital heart disease is uncommon beyond the first few months of life in developed countries, it is more common in developing countries with poor access to health care. Thus, it is useful to subdivide heart failure in this age group into left versus right heart failure (Table 73.1).

Left heart failure may occur in patients with structural heart disease and severe atrioventricular valve (i.e., atrioventricular septal defects or the tricuspid valve in congenitally corrected transposition) (13,14) or aortic insufficiency (i.e., ventricular septal defect–associated aortic valve prolapse) (15,16). Although progression of valve regurgitation may occur spontaneously over time, infective endocarditis is an important etiology of altered valvular function in this group of patients (17). Less commonly, patients with either progressive or undiagnosed severe left ventricular outflow obstruction may present with heart failure due to ventricular dysfunction (18).

An important cause of right heart failure in this group of patients is Ebstein anomaly of the tricuspid valve with an increase in the degree of tricuspid regurgitation with or without associated arrhythmias (19,20). Severe elevation of pulmonary vascular resistance associated with an intracardiac or great vessel shunt (Eisenmenger syndrome) may be associated with right ventricular dysfunction, tricuspid and/or pulmonary regurgitation, and right heart failure (21).

POSTOPERATIVE STRUCTURAL HEART DISEASE

More common is the patient who has undergone previous intervention (transcatheter or surgical) for structural heart disease. Such patients may develop left or right heart failure due to ventricular dysfunction, valve disease, residual shunts, and/or rhythm abnormalities (13,22).

Left heart failure may occur in the postoperative patient with ventricular dysfunction, a residual left-to-right shunt, outflow tract obstruction, or valve regurgitation (various combinations of these may coexist in any given patient). Examples include (a) aortic stenosis and/or insufficiency after previous

valvotomy (23–25), (b) truncal valve stenosis and/or regurgitation after repair (25,26), and (c) severe atrioventricular valve regurgitation after atrioventricular septal defect repair (27,28). Patients with a systemic morphologic right ventricle (D-transposition of great arteries after atrial baffle or congenitally corrected transposition of great arteries after repair) are at risk for ventricular dysfunction, tricuspid (systemic atrioventricular valve) regurgitation, and arrhythmias that may result in heart failure (29–36).

Right ventricular hypertension owing to pulmonary hypertension (37) or residual pulmonary outflow obstruction (native or conduit) (38) may progress after initial intervention and result in right heart failure. Right heart failure may also occur after previous intervention owing to significant pulmonary insufficiency, such as may occur after surgery for tetralogy of Fallot (39–41).

Patients who have undergone a Fontan procedure for single ventricle physiology represent another group at high risk for developing ventricular dysfunction, arrhythmias, and heart failure (33,42–46).

As stated previously, patients after catheter or surgical intervention for structural heart disease may develop either acute or chronic rhythm disturbances that may result in heart failure (44,47–49). Ventricular dyssynchrony can cause ventricular dysfunction and heart failure, with resynchronization therapy and optimization of atrioventricular delay emerging as an effective treatment modality in select patients (50–54).

STRUCTURALLY NORMAL HEART AND ACQUIRED HEART DISEASE

Acquired heart disease is a common cause of heart failure in this age group compared to younger children. Kawasaki disease (55) (KD) is the most common cause of acquired heart disease in children in the United States (56). Children younger than 5 years are most commonly affected (median 2 years). KD is a panvasculitis, and most of the morbidity and mortality in affected patients is due to coronary artery aneurysms and associated complications (57,58). Children may present with heart failure in the acute phase of KD due to myocarditis and myocardial dysfunction (59). Less commonly, pericarditis or valvulitis during the acute illness may contribute to clinical heart failure. Those who develop coronary sequelae may develop acute or chronic heart failure secondary to myocardial ischemia resulting in myocardial dysfunction with or without associated valve regurgitation (58).

Worldwide, rheumatic fever with carditis leading to rheumatic heart disease is the most common cause of acquired heart disease in children and young adults (60–62). Although classically described as pancarditis, the important abnormality in acute rheumatic carditis is valve dysfunction (mitral and/or aortic regurgitation); myocardial dysfunction does not occur (63,64). In 15% to 47% of cases of acute carditis, the valve regurgitation is severe enough to result in heart failure (65,66). The incidence of heart failure is even higher if recurrences are considered (67). Chronic rheumatic heart disease consists of variable combinations of mitral regurgitation/stenosis and aortic regurgitation/stenosis. The right heart is uncommonly involved. Heart failure may result from significant, progressive valve dysfunction (61,68,69). Less commonly, left ventricular dysfunction may develop secondary to chronic severe volume overload if significant mitral and/or aortic regurgitation are present. Although rheumatic mitral stenosis severe enough to result in symptomatic heart failure may occur in the first two decades of life in developing countries (70), chronic rheumatic heart disease with mitral stenosis

in the United States typically presents in the fourth to fifth decade of life (61,71).

Patients in this age group may also develop heart failure secondary to infective endocarditis. Such endocarditis usually occur in patients with underlying structural heart disease, but may occur in those with a normal heart especially with other risk factors (indwelling catheters, history of intravenous drug abuse, and staphylococcal bacteremia) (72,73).

Myocardial dysfunction owing to a wide range of causes may result in clinical heart failure in children and adolescents. Several infectious agents have been reported to cause myocarditis (most commonly enterovirus, adenovirus, and parvovirus) (7,9,74,75). In other cases, myocarditis may occur as part of a generalized inflammatory process, such as occurs with KD or connective tissue disease (76–78). Dilated CM may be a primary disorder or may occur secondary to myocarditis, coronary artery disease, or cancer treatment (anthracyclines and/or radiation) (79–85). A dilated cardiomyopathy may occur with a variety of storage diseases, mitochondrial disorders, or in association with myopathies (muscular dystrophy) (9). An increasing number of cardiomyopathies are being recognized as familial (86,87). Although less common than the dilated form, hypertrophic, restrictive, and left ventricular noncompaction cardiomyopathies may result in clinical heart failure, due to systolic and/or diastolic dysfunction (88–90). Although less common than in the neonate and infant, tachyarrhythmia-related (supraventricular tachycardia or atrial flutter) heart failure in children and adolescents has also been reported (91).

Other causes of heart failure in children and adolescents are worth noting. Patients with Marfan syndrome with mitral valve prolapse may develop heart failure if the mitral valve becomes progressively insufficient or aortic regurgitation progresses because of the progressive aortic root dilation (92). Sickle cell disease may be associated with myocardial ischemia or infarction (93). Renal dysfunction with systemic hypertension and fluid overload may result in left ventricular dysfunction (94,95). Conversely, primary or secondary (chronic lung disease or obstructive airways disease) pulmonary hypertension may result in right heart failure (96–98).

BIOMARKERS IN CHILDREN WITH HEART FAILURE

Biomarkers have been found to be valuable for diagnosis, prognosis, and monitoring response to therapy in patients with heart failure (99). The most established heart failure biomarkers are the natriuretic peptides (NPs). Four different NPs have been identified: (a) atrial natriuretic peptide (ANP), primarily released from the atria; (b) B-type natriuretic peptide (BNP), primarily released from the ventricles, (c) C-type natriuretic peptide (CNP), released from and acts on the vascular endothelium; and (d) D-type natriuretic peptide (DNP), isolated from ventricular myocardium (99–101). BNP was originally called brain natriuretic peptide because it was isolated from porcine brain. Subsequent studies showed BNP to be primarily released from ventricular myocytes. Both ANP and BNP can be produced by either the atria or the ventricles under pathologic hemodynamic conditions. Increased wall stress related to increased preload, increased afterload, or impaired systolic or diastolic ventricular function results in the synthesis of pre-pro-B-type NP (pre-proBNP). This is subsequently cleaved to proBNP, and then is further cleaved to the biologically active 32-amino-acid polypeptide (BNP) and an inactive aminoterminal fragment, N-terminal pro-BNP (NT-proBNP). The NPs have actions aimed at protecting the cardiovascular system from volume overload. BNP

results in smooth muscle relaxation with improved myocardial relaxation and vasodilation of the systemic, pulmonary, and coronary vascular beds. In addition, in the kidneys, the NPs result in diuresis and natriuresis. Further, the NPs inhibit the renin-angiotensin-aldosterone system, play a role in blunting the sympathetic nervous system, and inhibit endothelin release (contributing to vasodilation, diuresis, and natriuresis (99,100,102). Despite the fact that BNP and NT-proBNP are secreted in equal amounts and have levels that move concordantly in most clinical scenarios, it is important to note that the levels are not interchangeable. The half-lives are different, approximately 20 minutes for BNP and 1 and 2 hours for NT-proBNP in adults. The majority of young, healthy adults have BNP levels <25 pg/mL and NT-proBNP levels <70 pg/mL (99,101).

In adults, the serum levels of NPs (BNP and NT-proBNP) have been shown to be valuable in a number of clinical settings: (a) differentiating heart failure from pulmonary disease as the etiology for acute dyspnea, (b) increasing with diastolic dysfunction, (c) increasing with heart failure exacerbations, (d) increasing and having prognostic value in coronary artery disease, (e) increasing in the setting of pulmonary embolism, pulmonary hypertension, and chronic obstructive pulmonary disease, (f) increasing in high-output states (sepsis, cirrhosis, and hyperthyroidism), and (g) predicting subsequent events in patients with known heart failure (99,101,102).

From studies in adults, NP levels are known to vary with age, gender, obesity, renal disease, and other conditions. In pediatrics, it is important to note the striking variation of NP levels with age. BNP levels are higher at birth, peaking at 1 to 2 days of age, and then decreasing during the following days of life (103). In addition, the method and type of assay used can influence NP plasma values. Studies have reported on normal ranges of NPs during infancy and childhood (104–108). Serum concentrations of BNP and NT-proBNP suggestive of cardiac disease in children are shown in Table 73.2. Other studies have evaluated NPs in children in a variety of clinical settings, and there are a number of excellent reviews available (100,109–111). Table 73.3 lists the types of clinical settings, and Table 73.4 attempts to list selected studies, including cutoffs for use in the evaluation and management of patients.

TABLE 73.2 Serum Concentrations of BNP and NT-proBNP Suggestive of Cardiac Disease in Children

Age	NT-proBNP ^a (pg/mL)	Age	BNP ^b (pg/mL)
0–2 d	■ 12,000	0–2 d	■ 750

Patent ductus arteriosus (prematures)
Children with known congenital heart disease
Postoperative congenital heart disease
Anthracycline-treated children
Children after heart transplant
Children with pulmonary hypertension
Other conditions: Kawasaki disease, hypertrophic cardiomyopathy, end-stage renal disease, sepsis, after severe neurologic injury

Differentiating Lung Disease from Heart Disease

Both BNP and NT-proBNP have been found to be valuable for distinguishing between cardiac and pulmonary causes of respiratory distress in neonates and children. Significantly, higher BNP and NT-proBNP levels have been found in patients with heart failure than in those with lung disease (112–115).

Identifying Heart Disease in Children

Two studies have shown BNP to be valuable in children being evaluated for possible heart disease. In both studies, BNP was significantly higher in children with newly diagnosed significant heart disease than in children without significant heart disease (116,117).

Children with Known Heart Failure

From the data available, evaluation of BNP appears to be helpful for assessing prognosis and monitoring children with known heart failure. From two similar studies of children with chronic left ventricular dysfunction, BNP levels >~290 to 300 pg/mL predicted adverse events (death, hospitalization, listing for transplant) (118,119). A post-hoc analysis of patients with symptomatic systolic ventricular dysfunction from the carvedilol trial found elevated BNP of value in identifying patients at increased risk for HF event within 1 year (120). Studies of children with decompensated heart failure admitted to the intensive care unit found elevated BNP to be predictive of readmission or death (121) and serial BNP measurements to be of value in identifying patients who may need mechanical circulatory support (122).

Use in Neonates

Although levels are known to be higher in neonates, measurement of NPs may be of value in a few specific clinical scenarios. BNP has been shown to be higher in neonates with

TABLE 73.4 Natriuretic Peptides in the Evaluation and Management of Children

Condition	Age Range	N	NP	Cutoffs	Endpoints	Change in Risk	Reference
Patients with respiratory difficulty: differentiate HF and lung disease	1–36 mo	48	NT-proBNP	2,940 pg/mL	HF vs. lung disease	100% accurate	(113)
	Infants and children	49	BNP	40 pg/mL	HF vs. lung disease	84% accurate, 91% sens, 77% spec	(112)
	1 mo–17.5 y	76	NT-proBNP	727 pg/mL	HF vs. lung disease	97% accurate, 100% sens, 94% spec	(115)
Patients with possible heart disease	36 wk gestational age–19 y	100	BNP	170 pg/mL (neonates <7 d) 41 pg/mL (older patients)	Diagnosis of significant structural or functional heart disease	Neonates: 94% sens, 73% spec, 91% PPV Older: 87% sens, 70% spec, 77% PPV	(116)
	2 d–17.5 y	33	BNP	100 pg/mL	Diagnosis of critical heart disease (requiring admission to ICU)	100% sens, 98% spec	(117)
Outpatients with LV dysfunction	2 mo–21 y	53	BNP	300 pg/mL	Adverse events (cardiac death, hospitalization for cardiac reason, listing for transplant)	93% sens, 95% spec, 88% PPV, 97% NPV	(118)
	3 wk–16.6 y	92 (48 patients)	BNP	290 pg/mL	Adverse outcome (death, listing for transplant)	80% sens, 87% spec	(119)
Patients with HF admitted to ICU	2 d–21 y	82	BNP	760 pg/mL	Adverse outcome at 60 d after discharge (readmission or death)	74% sens, 93% spec	(121)
Premature babies	25–34 wk gestational age	66	BNP	1,110 pg/mL	Clinically significant and echocardiographically large PDA	100% sens, 95% spec	(126)
	30 wk (mean gestational age)	31	BNP	1,805 pg/mL	Lack of response of PDA to indomethacin	88% sens, 87% spec	(128)
Children with symptomatic HF	Age <18 y	138	BNP	140 pg/mL	Adverse event (hospitalization for worse HF, transplant, death)	71% sens, 63% spec	(120)
Children with CHD	1–37.5 y	62	BNP	40 pg/mL	Ventricular dysfunction	85% sens, 81% spec, 92% PPV, 68% NPV	(129)
Postoperative CHD	1 d–15.5 y	51	BNP (12 h postoperative)	540 pg/mL	Mechanical ventilation >48 h	89% sens, 83% spec	(138)
				815 pg/mL	Low cardiac output within 48 h	88% sens, 90% spec	
Children after heart transplant	10.5 y (median)	560 biopsies (86 patients)	BNP	100 pg/mL	Acute rejection, ISHLT ≥3A (biopsy)	For patients >1 y posttransplant, 96% sens, 99% NPV	(147)
	2 mo–20 y	53	BNP	700 pg/mL	Acute rejection, ISHLT ≥3A (biopsy)	100% sens, 92% spec, 100% NPV	(148)
	14–15 y (mean)	53	BNP	250 pg/mL	Death or retransplant in ensuing 90 d	Not given	(149)

BNP, B-type natriuretic peptide; CHD, congenital heart disease; HF, heart failure; NPV, negative predictive value; NT-proBNP, N-terminal B-type natriuretic peptide; PDA, patent ductus arteriosus; PPV, positive predictive value; sens, sensitivity; spec, specificity.

persistent pulmonary hypertension of the newborn (compared to babies with respiratory disease without elevated pulmonary pressures and babies without respiratory disease) (123). In neonates with congenital diaphragmatic hernia, elevated NT-proBNP correlated with pulmonary artery pressure and was associated with worse prognosis (124). In preterm neonates, elevated BNP is associated with a hemodynamically significant patent ductus arteriosus and may be valuable in predicting the need for medical or surgical intervention (125–128).

Children with Congenital Heart Disease

In the setting of congenital heart disease, BNP is increased in patients with ventricular dysfunction and may be predictive of subsequent events (129,130). In addition, BNP has been shown to correlate with the degree of shunting, right ventricular systolic pressure and pulmonary artery pressure, and pulmonary vascular resistance (131). Significant pulmonary insufficiency occurs after repair of some forms of congenital heart disease (most commonly tetralogy of Fallot), resulting in right heart volume overload and associated risk for right ventricular dysfunction, heart failure, and arrhythmias. In adolescents after repair of tetralogy of Fallot, NPs correlate with right ventricular hemodynamics and dilation (132,133). NPs have been reported to be of value for diagnosing heart failure in children with single ventricle physiology (134,135) and for identifying patients at risk for poor outcome (136), but a recent study suggests that routine measurement of NPs is not warranted in patients after the Fontan procedure (137). There is also suggestion that NPs may be useful in risk stratification of adults with CHD.

Postoperative Congenital Heart Disease

An elevated 12-hour postoperative BNP is associated with duration of mechanical ventilation and predictive of low cardiac output state (138). Another study found 24-hour postoperative BNP levels that are higher than preoperative levels to be associated with low cardiac output syndrome, more days of mechanical ventilation, and was predictive of poor postoperative outcome (139). Postoperative BNP has also been found to be associated with clinical heart failure scores in patients with single ventricle physiology (at various stages of palliation) (140), predictive of outcome in patients undergoing bidirectional cavopulmonary or total cavopulmonary connection for single ventricle (135), and NT-proBNP correlates with clinical heart failure in patients after the Fontan procedure (141). In pediatric patients requiring extracorporeal support following cardiac surgery, NPs may be useful in weaning (142), and an increase in BNP during a trial off of support is predictive of outcome (need for unplanned operation and survival) (143).

Anthracycline-Treated Children

Studies have shown BNP to be elevated in children with ventricular dysfunction late after treatment with anthracyclines and may have a role in the follow-up of these patients (144–146).

Children After Heart Transplant

Elevated or rising BNP levels in children after heart transplantation have been found to be valuable as a screening test for rejection (147,148) and for identifying patients at increased risk of death or retransplant (149,150).

Children with Pulmonary Hypertension

In children with pulmonary hypertension, a rising BNP correlates with hemodynamic and echocardiographic changes, and an elevated BNP is associated with decreased survival (151). In a different study of children with pulmonary hypertension, NT-proBNP correlated with functional class and 6-minute walking distance and was predictive of mortality (152).

Other Conditions

In addition to the scenarios described above, measurement of NPs may be valuable in other conditions. BNP and NT-proBNP were found to be a useful marker for the myocarditis of KD and may have value in differentiating KD from a viral illness (153). A recent study reported an association between BNP and development of coronary artery lesions (154). BNP levels have been reported to correlate with noninvasive parameters of disease severity in children with hypertrophic cardiomyopathy, including diastolic dysfunction (155). BNP levels may be elevated in patients with end-stage renal disease, independent of heart dysfunction. Nonetheless, even in this population, BNP levels may be predictive of ventricular dysfunction, cardiac events, and survival (156). NT-proBNP levels should be interpreted cautiously in children with sepsis since patients with normal ventricular function may have elevated NT-proBNP levels (157). Finally, in patients with severe central nervous system injury who progress to brain death, mechanisms other than myocardial performance appear to regulate BNP levels (elevated despite normal function and ultimately good outcome after use as a donor heart for transplant), limiting the value of these levels in this patient population (158).

TREATMENT OF CHRONIC HEART FAILURE

One could argue that the term “heart failure” is somewhat of a misnomer for the clinical syndrome of large left-to-right shunt with pulmonary overcirculation. However, many of the same neurohormonal abnormalities are present in these patients that are present in patients with congestive heart failure owing to systemic ventricular dysfunction. Patients with large left-to-right shunts are tachypneic, tachycardic, and diaphoretic. They have elevations in plasma norepinephrine and aldosterone levels (159,160). However, the treatment of this clinical syndrome usually entails surgical correction of the underlying anatomic problem.

Treatment strategies utilized in the management of chronic heart failure owing to systemic ventricular dysfunction in children have been almost entirely derived from large multicenter, randomized, placebo-controlled trials in adults with heart failure due to left ventricular systolic dysfunction. Some of these studies are restricted to adults with either ischemic cardiomyopathy or only nonischemic (dilated) cardiomyopathy (161), although most studies include adults with both ischemic and nonischemic cardiomyopathy. Even in those adults with nonischemic CM, there are significant comorbidities not seen in children with heart failure, such as diabetes and hypertension, that make extrapolation of treatment strategies from these adults to children with dilated CM problematic (162). Within the limitations of extrapolating data from adult studies of this kind, pediatric cardiologists have adapted many of the treatments that are currently recommended for adults with heart failure owing to left ventricular systolic dysfunction (163). This section reviews the current evidence base for the treatment of chronic heart failure in children in addition to current recommendations based on small case series and published anecdotal experience.

Once a child has been diagnosed with chronic heart failure, therapeutic strategies are directed toward the underlying cause of the heart failure. In patients with “heart failure” due to left-to-right shunt (e.g., ventricular septal defects, single ventricle without pulmonary stenosis) and resultant pulmonary overcirculation, surgical intervention is currently the treatment of choice in virtually every situation. If, for some reason, surgery is not an option (e.g., small size of the patient, no surgical options available), there are some potential medical interventions that may improve symptoms. These include diuretics, angiotensin-converting enzyme (ACE) inhibitors, and possibly beta-adrenergic receptor (beta) blockers. Diuretics are the mainstay of therapy in this situation through their ability to reduce pulmonary edema and systemic congestion (see below). There is some evidence that ACE inhibitors may be beneficial through their ability to reduce systemic vascular resistance in preference to pulmonary vascular resistance and thus reduce pulmonary blood flow (164–166). There is also evidence that beta-blockade with propranolol may be beneficial to infants in this situation. Bucchorn et al. have demonstrated that propranolol can reduce heart rate, respiratory rate, and heart failure symptoms as well as improve growth in infants with heart failure owing to large left-to-right shunts (160,167,168).

In children with heart failure caused by isolated systemic ventricular systolic dysfunction, there are usually no good surgical options short of heart transplantation. Thus, it is incumbent on the pediatric cardiologist to maximize medical therapy and avoid or delay heart transplantation in as many children as possible. Unfortunately, there is very little evidence base from which to derive guidance for which medications are best in which situations and at which dosages. For older children with dilated cardiomyopathy, it may be reasonable to extrapolate from some of the larger trials in adults with nonischemic cardiomyopathy. In children with heart failure with congenital heart disease and possibly a systemic ventricle that is not a left ventricle, it is much less clear how appropriate it is to extrapolate from these adult studies. We present here what is known about the use of medications and devices in the treatment of adults with chronic heart failure. Where possible, we also present existing data in children.

DIURETICS

With the exception of aldosterone antagonists, conventional diuretics used in the treatment of heart failure consist of agents that block specific ion transport proteins in tubular cells and thereby inhibit the reabsorption of solutes (169). Although diuretics have never been shown to improve survival in heart

failure, they are considered to be essential to the treatment of fluid overload in patients with heart failure. They relieve symptoms of heart failure and decrease systemic and pulmonary vascular pressures (170). A recent multicenter study in adults demonstrated that there were no significant differences in patients’ global assessment of symptoms or in the change in renal function when diuretic therapy was administered by bolus as compared with continuous infusion or at a high dose as compared with a low dose (171). Some patients with heart failure do not require diuretics, but the majority of symptomatic patients with heart failure will require some diuretic therapy. Table 73.5 summarizes some commonly used oral diuretics in children. These non-potassium-sparing diuretics have potential adverse consequences even while reducing systemic and pulmonary venous congestion. They have been shown to activate the renin-angiotensin-aldosterone system and the sympathetic nervous system (172), in addition to adversely affecting renal function. For this and other reasons, some have advocated using ultrafiltration in adults with heart failure and fluid overload, rather than treatment with diuretics (173). In infants, diuretics cause an increase in plasma renin levels in those with large left-to-right shunts (160). Some patients with heart failure can develop resistance to loop diuretics. Possible reasons for this include noncompliance, simultaneous use of nonsteroidal anti-inflammatory drugs, and diminished renal natriuretic effect owing to compensatory hypertrophy and hyperplasia of epithelial cells of the distal convoluted tubule leading to increased reabsorption of sodium (174). Once noncompliance has been excluded, one should try higher doses and more frequent administration of loop diuretics and possibly add a thiazide diuretic. The thiazide diuretic, metolazone, administered in conjunction with a loop diuretic can be uniquely successful in effecting diuresis in edematous or diuretic-resistant patients (175).

Although spironolactone and eplerenone are potassium-sparing diuretics, their beneficial effects in heart failure are probably less related to their diuretic effects than other effects. Plasma aldosterone levels can reach as much as 20 times normal in adults with heart failure, both because of increased production and decreased rate of hepatic clearance (176). In addition to its effects on salt and water homeostasis, aldosterone has multiple other effects including decreased endothelial vasomotor reactivity and increased myocardial fibrosis (177). Two studies have demonstrated that aldosterone antagonists, spironolactone and eplerenone, both reduce mortality and hospitalization in adults with heart failure when compared to placebo (178,179). In the latter study, there was a significantly increased risk of hyperkalemia and a significantly decreased risk of hypokalemia in patients treated with eplerenone compared to placebo (179). The list of potential mechanisms by

TABLE 73.5 Commonly Used Oral Diuretics in Pediatrics

Drug	Class	Action	Dose	Interval	Maximum Daily Oral Dose
Furosemide	Loop	Inhibit Na ⁺ Cl ⁻ K ⁺ cotransport, ascending loop of Henle	0.5–2 mg/kg/dose	bid—qid	600 mg
Bumetanide	Loop	Same as above	0.015–0.1 mg/kg/dose	qd—bid	10 mg
Chlorothiazide	Thiazide	Inhibit Na ⁺ Cl ⁻ cotransport, distal tubule	10–20 mg/kg/dose	bid	2,000 mg
Hydrochlorothiazide	Thiazide	Same as above	1–2 mg/kg/dose	bid	200 mg
Metolazone (as Zaroxolyn)	Thiazide	Same as above	0.2–0.4 mg/kg/24 h	qd—bid	20 mg

TABLE 73.6 Summary of Landmark Enalapril Trials in Adult Heart Failure

Study	Patient Population	ACE Inhibitor	Treatment Duration	Outcome
CONSENSUS	NYHA IV (<i>n</i> = 253)	Enalapril vs. placebo	1 d–20 mo	Decreased mortality; decreased HF
SOLVD treatment	NYHA II and III (<i>n</i> = 2,569)	Enalapril vs. placebo	22–55 mo	Decreased mortality; decreased HF
V-HeFT II	NYHA II and III (<i>n</i> = 804)	Enalapril vs. hydralazine, isosorbide	0.5–5.7 y	Decreased mortality; decreased sudden death

HF, heart failure; NYHA, New York Heart Association.

which aldosterone antagonism benefits patients with heart failure continues to grow (180). There is increasing evidence that aldosterone antagonists may be beneficial in all stages of symptomatic heart failure, including those with mild symptoms (181).

DIGOXIN

The main mechanism of action of digoxin is to inhibit the sodium–potassium ATPase pump in the myocardium. This promotes sodium–calcium exchange and increases intracellular calcium and thus contractility. Digoxin also has beneficial modulating effects in the neurohormonal system: improvement in baroreceptor function, increased vagal tone, sympathoinhibitory effects, decreased circulating norepinephrine levels, and possibly aldosterone antagonistic effects (182). In adults with heart failure owing to left ventricular systolic dysfunction, digoxin is currently indicated only in those patients with symptoms or a history of symptoms (163). The Digitalis Investigators Group (DIG) trial showed no differences in mortality in those treated with digoxin and those treated with placebo over a 3-year period, although there were significantly fewer cardiovascular hospitalizations in the digoxin-treated group (183). The Randomized Assessment of Digoxin on Inhibitors of Angiotensin Converting Enzyme (RADIANCE) trial demonstrated that patients withdrawn from digoxin had significantly worsened heart failure symptoms and exercise tolerance (184). In another digoxin-withdrawal trial, the Prospective Randomized study of Ventricular failure and the Efficacy of Digoxin (PROVED) trial, patients with heart failure who received digoxin had a lower incidence of worsening heart failure and hospitalizations for heart failure, a higher left ventricular ejection fraction (LVEF), and better treadmill exercise time than patients who received placebo (185). Optimal dosing of digoxin is still a matter of debate. Post-hoc analyses of the DIG trial examined mortality as a function of serum digoxin concentrations and found that higher serum digoxin concentrations were associated with a higher mortality, suggesting a possible benefit from lower serum digoxin concentrations in patients with heart failure (186,187).

The role of digoxin in children with chronic heart failure is even less clear. Some studies have suggested a benefit from digoxin in children with heart failure owing to large left-to-right shunt, whereas others have not (188,189). One study suggests that digoxin may actually adversely affect this clinical situation by causing an acute increase in pulmonary blood flow and left atrial pressure (190). In the setting of decreased

systemic ventricular systolic function, no data are available in children to guide therapy; thus one must consider cautiously extrapolating from adult heart failure studies as described above.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACE inhibitors are currently recommended for the treatment of asymptomatic and symptomatic adults with decreased left ventricular systolic function (191). ACE, which is the same as kininase II, is a bivalent dipeptidyl carboxyl metalloproteinase present as a membrane-bound form in endothelial cells, in epithelial or neuroepithelial cells, in the brain, and as a soluble form in blood and numerous bodily fluids (192). ACE inhibitors have favorable effects on hemodynamics in patients with heart failure due to systolic dysfunction through their ability to reduce afterload, preload, and systolic wall stress, with a resultant increase in cardiac output without an increase in heart rate. Several studies in adults with left ventricular systolic dysfunction have shown that ACE inhibitors improve survival and symptoms in adults with symptomatic heart failure and improve survival in adults with asymptomatic heart failure (193–196) (Table 73.6). Although the optimal dosing of ACE inhibitors in adults is not well defined, there is some evidence that, in the absence of side effects, intermediate or higher doses may be more beneficial than lower doses (197,198). As stated above, there is some evidence from non-randomized studies in children that ACE inhibitors may benefit some children with large left-to-right shunts (164–166). However, there are few reports of ACE inhibitors benefiting children with heart failure due to systemic ventricular systolic dysfunction (199,200). The first randomized, placebo-controlled trial of ACE inhibitors in children with heart disease was performed in 18 patients after the Fontan operation who were randomized to either placebo or enalapril (201). There was no difference between groups using the primary endpoint of exercise capacity after 10 weeks of therapy. Furthermore, the mean percent change in the cardiac index from rest to maximal exercise was significantly *decreased* in the enalapril group compared to the placebo group. However, these patients were not in heart failure at the time of the study, and exercise capacity has been shown to be problematic as a primary endpoint in heart failure trials (202,203). Thompson et al. performed a prospective comparison of 36 children undergoing a Glenn procedure at two different hospitals, 18 of whom received perioperative

enalapril and 18 who did not (204). They found that there was a shorter duration and amount of pleural drainage in those who received enalapril compared to those who did not. A recently completed placebo-controlled, randomized trial found that administration of enalapril to infants with single-ventricle physiology in the first year of life does not improve somatic growth, ventricular function, or heart failure severity (205).

ANGIOTENSIN RECEPTOR BLOCKERS

Angiotensin II receptor blockers (ARBs) directly block the effects of angiotensin II at the receptor level. There are theoretical advantages of ARBs over ACE inhibitors. For instance, ARBs do not increase bradykinin levels as ACE inhibitors do, an effect that is responsible for the common adverse effect of cough seen with ACE inhibitors. One of the first studies comparing an ACE inhibitor (captopril) with an ARB (losartan), the Evaluation of Losartan in the Elderly (ELITE) trial, showed no difference in the primary endpoint (heart failure hospitalizations) in elderly patients with heart failure, but an unexpected statistically significant improvement in survival with losartan (206). However, the follow-up study, ELITE II, failed to show a significant survival benefit from ARBs over ACE inhibitors (207). In the Valsartan in Heart Failure Trial (ValHeFT), the ARB valsartan or placebo was added to therapy including digoxin, diuretics, ACE inhibitors, and beta-blockers. The addition of valsartan had no effect on all cause mortality but provided a 13% reduction in combined morbidity and mortality (208). On the basis of these and other studies, the use of ARBs is currently only recommended for patients with heart failure who are unable to tolerate ACE inhibitors. The little data available on the use of ARBs in children are primarily limited to its use in pediatric hypertension (209–212).

BETA-ADRENERGIC RECEPTOR BLOCKERS

Before Waagstein et al. first described the successful use of beta-blockers in a small group of adults with heart failure, these medications were thought to be contraindicated in patients with heart failure (213). Many small studies throughout the 1980s and early 1990s suggested a benefit of beta-blockers in adults with heart failure (214–217). However, it was not until 1996 that two studies demonstrated a significant benefit of beta-blockers in adults with heart failure with regard to symptoms, left ventricular systolic function, and survival (202,203).

There are many proposed mechanisms through which beta-blockers improve left ventricular function, symptoms, and survival in patients with heart failure (218). Although different beta-blockers may have different effects in patients

with heart failure, the available data support the hypothesis that the primary mechanism of action of beta-blocking agents in chronic heart failure is to prevent and reverse adrenergically mediated intrinsic myocardial dysfunction and remodeling (219). On a cellular level, sustained cardiac adrenergic activation results in desensitization of beta-adrenergic signal transduction mechanisms and direct damage to cardiac myocytes (219). Clinically, this results in ventricular dysfunction and remodeling (chamber dilation and assumption of a more spherical shape) and ultimately the development of heart failure. Various other mechanisms of action have been proposed for the beneficial effects of beta-blockers in heart failure, including upregulation of beta-adrenergic receptors. Failing human hearts have decreased catecholamine sensitivity and beta-adrenergic receptor density, suggesting that regulation of beta-adrenergic receptors may be an important variable in heart failure (220). However, upregulation of beta receptors must not be a major mechanism of action of beta-blockers since some beta-blockers that are efficacious in the treatment of heart failure, such as metoprolol, upregulate beta-receptors, whereas others that are at least as efficacious, such as carvedilol, do not upregulate beta-receptor density (221). Other potential mechanisms of the beneficial effects of beta-blockers in heart failure include decreased stimulation of other neuro-hormonal systems, antiarrhythmic effects, coronary vasodilation, negative chronotropic effects, antioxidant effects, and improved myocardial energetics (222). Individual beta-blockers may also have unique properties that may be beneficial in heart failure. For instance, carvedilol and several of its metabolites are potent antioxidants that may inhibit catecholamine toxicity through the ability of catecholamines to generate oxygen free radicals in the myocardium (223).

Heart failure trials in adults have shown that both metoprolol and bisoprolol improve symptoms and survival in adults with mild-to-moderate heart failure (224,225), and that carvedilol improves symptoms and survival in adults with severe heart failure (226). These trials are summarized in Table 73.7. Based on this evidence, beta-blockers are currently recommended treatment for symptomatic or asymptomatic left ventricular dysfunction in adults (191). Both metoprolol and carvedilol are currently recommended for the treatment of chronic heart failure in adults. Several studies have now shown an advantage of carvedilol over metoprolol (227).

Many small nonrandomized reports of beta-blockers in children with heart failure had suggested possible benefit in this group (228–230). The Pediatric Carvedilol trial was a multicenter, placebo-controlled, double-blind, parallel-group study that randomized 161 children with symptomatic heart failure secondary to systemic ventricular dysfunction to receive either placebo, lower dose, or higher dose carvedilol on top of background heart failure medications (231). The primary endpoint was a composite measure of clinical heart failure outcomes, and patients were determined to have a response to therapy

TABLE 73.7 Summary of Landmark Beta-Blocker Trials in Adult Heart Failure

Study (Year)	Beta-Blocker	# Pts/NYHA Class	Endpoint	Survival Benefit
Mocha (1996)	Carvedilol	345/NYHA 1–3	Submaximal exercise	Dose-dependent survival
U.S. Coreg (1996)	Carvedilol	1094/NYHA 1–3	Submaximal exercise	67%
MERIT-HF (1999)	Metoprolol	3,991/NYHA 1–3	All-cause mortality	35%
CIBIS-II (1999)	Bisoprolol	2,647/NYHA 1–3	All-cause mortality	29%
COPERNICUS (2001)	Carvedilol	2,289/Severe HF	All-cause mortality	35%

of worsened, improved, or unchanged. The study showed a surprisingly high rate of improvement in the placebo group (56%) and failed to show any difference between placebo and carvedilol on the primary outcome. However, a prespecified analysis of the improved versus not improved outcome showed a significant interaction between study drug and ventricular morphology, suggesting a possible differential effect of the treatment between patients with a systemic left ventricle (beneficial trend) and those whose systemic ventricle was not a left ventricle (nonbeneficial trend) ($p < 0.02$). Post-hoc analyses of this study found that in children with moderately symptomatic heart failure, BNP levels ≥ 140 pg/mL, age > 2 years, and abnormal echocardiographic myocardial performance indices identified subjects at higher risk for worse outcome (232,233).

DEVICE THERAPY FOR HEART FAILURE

Two major advances in the treatment of heart failure and prevention of sudden death are the use of devices in adults: cardiac resynchronization therapy (CRT) and implantable cardioverters/defibrillators (ICDs). Studies in adults have shown that CRT can improve symptoms, exercise tolerance, quality of life, echocardiographic indices of left ventricular performance, and survival in adults with heart failure and interventricular conduction delays (234–236). CRT is now recommended for adults with symptomatic heart failure and electrical dyssynchrony manifested as an interventricular conduction delay. There is evidence that selected patients without electrical dyssynchrony (e.g., those with a normal QRS duration) may, however, have mechanical dyssynchrony that may benefit from biventricular pacing and resynchronization therapy. It may be possible to identify such patients by using tissue Doppler imaging or other such techniques (237,238). These techniques are becoming increasingly validated in children (239). There are few data regarding the use and indications of CRT in children. One study in seven children with congenital heart disease and a right bundle branch block pattern found that resynchronization therapy resulted in small, but statistically significant, acute improvements in cardiac output and right ventricular dp/dt (50). Standard right ventricular pacing without careful manipulation of the atrioventricular interval may be insufficient to shorten the QRS duration in patients with tetralogy of Fallot and right bundle branch block (240). Experience with the use of CRT in children with systemic ventricular dysfunction and heart failure is modest, but increasing. A recent single-center experience with CRT in 60 consecutive children demonstrated benefit in the majority of patients, although there were significant challenges associated with implantation (53). However, the heterogeneous patient population, technical limitations from patient size, vascular access issues, and unique forms of ventricular dyssynchrony make it difficult to determine risks and benefits of this procedure in children (54,241).

Patients succumb to heart failure from either pump failure or from sudden death. Although the mode of sudden death is often not known, it is speculated that a many of these deaths are due to tachyarrhythmias, particularly ventricular tachycardia and ventricular fibrillation (242). Because of this, multiple prospective, randomized trials have assessed the utility of ICDs in patients with heart failure. The Antiarrhythmics Versus Implantable Defibrillator (AVID) trial and the Canadian Implantable Defibrillator Study (CIDS) demonstrated that ICDs produced approximately a 30% reduction in relative risk of sudden cardiac death in adults with a history of malignant ventricular arrhythmias (243,244). After demonstrating possible benefit of ICDs in secondary prevention of sudden cardiac death, the next step was to see if this therapy could be applied to primary prevention. The Multicenter Automatic Defibrillator Implantation Trial (MADIT) (245), the

Multicenter Unsustained Tachycardia Trial (MUSTT) (246), and MADIT II (245) all showed mortality benefit from ICDs in adults with coronary artery disease and reduced LVEF. The Comparison of Medical Therapy, Pacing, and Defibrillation in Chronic Heart Failure (COMPANION) study for the first time demonstrated survival benefit of CRT and combined device (biventricular pacemaker with defibrillator capacity) therapy in heart failure (247). Similarly, the MIRACLE ICD trial demonstrated that combined CRT and ICD therapy in adults with left ventricular systolic dysfunction, moderate-to-severe heart failure, and prolonged QRS duration resulted in improved quality of life, functional status, and exercise capacity when compared to placebo (235). Finally, the SCD-HeFT trial demonstrated a clear survival benefit in adults treated with an ICD, when compared to either placebo or amiodarone (248). The incidence of sudden death in children with heart failure appears to be significantly less than that seen in adults with heart failure (249,250). Although still controversial, there are guidelines for the use of ICDs in children, some of which has been extrapolated from adult trials (251,252).

Despite all of these available therapies, there is still significant concern that current transplant-free survival is not significantly better than in previous eras when the only therapies available were digoxin and diuretics (253). The possible reasons for this remain elusive, but clearly provide stimulus for continued research into the differences between adult and pediatric heart failure and into finding new pharmacologic therapies for children with heart failure.

Neurodevelopmental Outcomes after Heart Surgery in Children

Caren S. Goldberg ■ Jane W. Newburger

The survival of children with congenital heart disease has improved dramatically over the past four decades; indeed the number of adults with congenital heart disease is now believed to exceed the number of children (1,2). As mortality has declined, neurologic and developmental morbidities in survivors have come increasingly into focus. Poor school performance and the resultant need of educational support across the developmental span from kindergarten through 12th grade may have considerable personal and societal costs. Furthermore, the increasing number of adults with congenital heart disease has highlighted the consequences of neurodevelopmental impairments for employability and mental health (3). Neurodevelopmental disabilities can derive from innate or genetic factors; from aberrant fetal circulation; from the physiology and sequelae of congenital heart disease itself (e.g., chronic severe cyanosis, failure to thrive, cardiac arrests secondary to arrhythmia); or from the procedures, such as cardiac catheterization or cardiac surgery, used to treat congenital heart disease. Particularly in congenital heart disease, it can be difficult to separate developmental outcomes for particular diagnoses and their genetic underpinnings from consequences of surgical and transcatheter procedures used in their management. It is likely that central nervous system effects of congenital heart disease are cumulative and affected by the complex interaction of genetic, preoperative, intraoperative, and postoperative factors (4,5). In this chapter, we review variables that contribute to neurodevelopmental outcomes in children after heart surgery and summarize findings related to long-term neurodevelopmental outcomes for more common, complex congenital heart malformations.

GENETIC ABNORMALITIES

Chromosomal abnormalities may cause both congenital heart defects and abnormalities of central nervous system structure and function. Examples include chromosomal disorders (e.g., trisomy 13, 18, or 21), microdeletions (e.g., velocardiofacial syndrome secondary to 22q11 microdeletion), or mutations (e.g., Williams syndrome, Alagille syndrome, or CHARGE syndrome). The genetic causes of other syndromes with congenital anomalies, such as VATER syndrome, are unknown. Children with genetic syndromes have much worse neurodevelopmental outcome than those without recognizable syndromes (6). Furthermore, it is suspected that genetic factors may underlie delayed development without other explanation even in some patients without a recognizable constellation of congenital abnormalities.

Specific types of congenital heart defects may be associated with different chromosomal abnormalities with varying molecular pathways that impact central nervous system structure and function. For example, tetralogy of Fallot (TOF) can be associated with mutation or deletion of several different

genes (NKX2.5, JAG1, TBX5, TBX1, and FOXC2) and with several clinical syndromes, such as velocardiofacial syndrome or trisomy 21 (7,8). Three genes known thus far to cause TOF (i.e., TBX5, NKX2.5, and JAG1) have been found in the brain as well as the heart (<http://www.ncbi.nlm.nih.gov>, UniGene). JAG1, mutated in Alagille syndrome, encodes a ligand for the notch intercellular signaling pathway of tremendous importance in brain development (9–13), and 16% of patients with Alagille syndrome have mental retardation (14). In TOF patients without other features of Alagille syndrome, polymorphisms in JAG1 may be associated with both cardiac and neurocognitive phenotypes.

Mutations causing congenital heart defects may be associated with specific neurodevelopmental profiles. For example, although the clinical phenotype associated with 22q11 microdeletion is variable (15), a reasonably consistent neurodevelopmental profile has emerged. Intelligence quotient (IQ) can range from profound mental retardation (16) to average range (17–21), with the prevalence of learning disabilities approaching 100% (18). In adults with velocardiofacial syndrome, specific deficits have been reported in visual-spatial ability, problem solving and planning (executive functions), abstract social thinking, and attentiveness (20,22,23). Studies in children report that verbal IQ tends to exceed performance IQ, with velocardiofacial syndrome patients displaying relative strengths in rote verbal knowledge and memory and relative weaknesses in visual-spatial and perceptual skills and mathematical abilities (24,25). Finally, the 22q11 microdeletion is associated with increased psychiatric risk (16,20,25–28). In adults with 22q11 microdeletion, the prevalence of late-onset psychosis, most commonly schizophrenia and schizoaffective disorders, is 10% to 20% (18,29,30). With advances in research on genetic causes of congenital heart disease, it is likely that an increasing number of genetic abnormalities will be linked to neurologic and developmental outcomes in congenital heart disease patients.

BRAIN ANATOMY, PATHOLOGY, AND NEUROIMAGING

Cerebral dysgenesis has been reported in autopsy series to occur in 10% to 29% of children with congenital heart disease and may include such features as microdysgenesis, incomplete operculization, microcephaly, and agenesis of the corpus callosum (5,31–34). The incidence varies by lesion and is particularly high in hypoplastic left heart syndrome (HLHS) (31–33,35). The cause of cerebral dysgenesis may be related to genetic factors or to abnormalities of fetal cerebrovascular flow dynamics caused by particular congenital heart defects. For example, fetuses with HLHS, whose cerebral perfusion is supplied retrogradely through the ductus arteriosus, as well as those with hypoplastic right heart syndrome and other

congenital defects, have been shown to have cerebrovascular resistance that is lower than normal (36,37).

Fetuses with congenital heart disease and with low cerebral-to-placental resistance ratios (<1) have smaller head circumferences than normal (37). Multiple studies have demonstrated an association of smaller brains and congenital heart disease (37–40). Recently, Limperopoulos et al. (39) performed brain magnetic resonance imaging (MRI) on third-trimester fetuses with a variety of congenital cardiac malformations and found that compared to fetuses with normal cardiac anatomy, with adjustment for gestational age and weight, those with cardiac malformations had smaller brain volumes and impairment of neuroaxonal development and metabolism. In addition, work by Schaer et al. (40) supports the interaction of hemodynamic consequences of congenital heart disease with genetic background on neurologic development. These investigators performed MRI on 53 patients with 22q11.2 deletion and found that compared to healthy controls, cerebral volume was 6.9% less; yet in those patients with 22q11.2 deletion and associated congenital heart disease that required cardiac surgery, cerebral volume reduction was 16.9% (40).

In addition to cerebral dysgenesis, infarction may be seen on histopathologic examination of the brains of infants and children with congenital heart disease. Thromboembolic events related to cardiac catheterization, cardiac surgery, or endocarditis may cause focal infarction. Decreased cerebral perfusion, related to hypotension, hypoperfusion, or cardiac arrest, is associated with a diffuse pattern of cerebral injury (41). Kinney et al. (42) analyzed the neuropathology of 38 infants who died after undergoing reparative or palliative cardiac surgery. Although a spectrum of gray matter lesions was evident, cerebral white matter damage, composed of either periventricular leukomalacia or diffuse white matter gliosis, was the most significant finding. Neonates were more likely than infants to have periventricular leukoencephalopathy, reflecting the vulnerability of the immature (premyelinating) white matter to hypoxic-ischemic injury. Otherwise, the timing and type of surgery were unrelated to the pattern and severity of overall brain injury.

Brain MRI allows the opportunity to evaluate brain structure and pathology in living patients, both preoperatively and postoperatively. In the preoperative period, McConnell et al. (43) found that one-third of infants undergoing cardiac surgery had ventriculomegaly and enlargement of subarachnoid spaces consistent with cerebral atrophy. The Total Maturation Scoring System developed by Childs to measure brain maturation in premature infants incorporates information related to myelination, cortical infolding, glial cell migration bands, and presence of germinal matrix tissue (44). Licht et al. (45) using this score found neonates with HLHS and dextro-transposition of the great arteries (D-TGA) to have structural immaturity of the brain, on average delayed by 1 month (45), compared to healthy neonates. Utilizing this same measurement of brain maturation, Andropoulos et al. (46) demonstrated that postoperative neurologic injury as measured by MRI was greater in newborns undergoing cardiac surgery with less mature brain development. Mahle et al. (47) reported that among 24 infants undergoing cardiac surgery, preoperative MRI revealed periventricular leukoencephalopathy in 16% and infarct in 8%. Moreover, preoperative cerebral lactate peaks were elevated in more than half of infants evaluated by magnetic resonance spectroscopy. In the early postoperative period, 48% of infants had new periventricular leukoencephalopathy, 19% had new infarcts, and 33% had new parenchymal hemorrhage. Interestingly, on late postoperative MRI, performed in 17 infants, all previously detected periventricular leukoencephalopathy had resolved. However, cerebral atrophy was detected in two, old infarct in one, and new infarct in one subject. Similarly, Galli et al. (48) detected periventricular leukoencephalopathy

in 54% of neonates and 4% of infants who underwent brain MRIs in the period between 6 and 14 days following open heart surgery. While the predictive value of MRI findings on longer term developmental outcome remains unclear, evidence is accumulating that preoperative brain abnormalities, as well as brain injury suffered in the intraoperative and postoperative periods, contribute to neurodevelopmental sequelae in children with congenital heart disease.

PERIOPERATIVE RISK FACTORS

Most prospective studies of central nervous system protection and injury have focused on risk factors related to open heart surgery and the perioperative period. The intense attention to perioperative risk factors is likely related to the ability of investigators to study the brain during this high-risk period, which includes planned brain ischemia-reperfusion injury with use of hypothermic cardiopulmonary bypass and total circulatory arrest techniques. Furthermore, perioperative management strategies can be tested in randomized clinical trials.

Perioperative Monitoring Approaches

As investigators have sought to optimize neurodevelopmental outcomes by modifying surgical and medical perioperative approaches, a limiting factor has been identification of early predictive markers of longer term developmental outcomes. To date, MRI has been performed primarily in a research setting. However, some centers have adopted perioperative monitoring strategies that can include continuous electroencephalogram, near-infrared spectroscopy, and/or transcranial Doppler ultrasound (46,49,50). Clinical adoption of these monitoring techniques has outpaced establishment of definitive evidence of clinical benefit. However, recently, Kussman et al. (51) found that among infants undergoing cardiac operation for biventricular repair, decreased cerebral oxygen delivery as measured by near-infrared spectroscopy during the perioperative period was associated with lower scores on the Psychomotor Development Index (PDI) and increased abnormalities found at brain MRI. Further study of this technique, other perioperative monitoring approaches, and additional potential early markers are needed to better understand how late outcomes can be predicted in newborns and infants undergoing cardiac surgery. Nonetheless, a great deal has been learned since the 1990s related to perioperative risk factors of central nervous system insults for children with congenital heart disease.

Intraoperative Support Techniques

Repair of congenital heart disease requires the use of cardiopulmonary bypass, in which blood is exposed to artificial surfaces. This, in turn, causes a massive systemic inflammatory response, with induction of proinflammatory cytokines, chemokines, and endotoxin, as well as activation of the complement system, leukocytes, and the endothelium (52). Furthermore, cardiopulmonary bypass is accompanied by risks of gaseous and particulate embolism, macroemboli, and hypoperfusion resulting in diffuse ischemia/reperfusion injury (53).

During the most complex cardiac operations in the neonate, vital organ support is accomplished using deep hypothermia with low-flow continuous cardiopulmonary bypass (low-flow bypass) and/or deep hypothermic circulatory arrest (DHCA) (54–56). These techniques are often used sequentially in the same patient. Hypothermia is the principal technique used to protect vital organs during use of low-flow bypass or DHCA (57). Its effects are derived, in part, from a reduction in

metabolic activity, reflected in reduced oxygen consumption. Additional mechanisms of hypothermic protection of the brain and other organs during ischemia include preservation of intracellular stores of high-energy phosphates and of high intracellular pH, as well as protection against reperfusion injury including the no-reflow phenomenon, calcium influx, and free radical damage (57).

Circulatory arrest has been widely used since the 1960s in centers with expertise in infant open-heart surgery. This technique has advantages for the surgeon of absence of perfusion cannulae and of blood from the operative field, though it is thought to increase the risk for neurologic insult. In recent years, regional (antegrade) cerebral perfusion has been advocated to avoid exposure to DHCA (58,59) during neonatal aortic arch reconstruction. However, one single-center randomized trial did not show any benefit of regional cerebral perfusion, compared to DHCA, as a method of vital organ support during the Norwood operation with respect to developmental outcomes before Stage II surgery or at 1 year of age, (60). In addition, using MRI, Dent and colleagues found that the rate of new periventricular leukomalacia in the postoperative period was not reduced by the use of regional cerebral perfusion, compared to historical controls who underwent Norwood operation with a DHCA-only strategy (61).

When evaluated as a continuous variable, longer duration of total circulatory arrest has been associated with increased risk of seizures, choreoathetosis, release of brain isoenzymes, and developmental delay (21,62–71), though in some studies, duration of circulatory arrest has not been a significant predictor of outcome (60,73). The absence of an effect may be related, in part, to a narrow range of circulatory arrest times, small sample sizes, or overwhelming effects of other risk factors for adverse outcome, such as underlying genetic abnormalities or severe hemodynamic instability in the preoperative or postoperative period. However, Wypij et al. (74) analyzed the relationship of duration of total circulatory arrest to neurodevelopmental outcomes at age 8 years in infants with D-TGA who underwent the arterial switch operation in the neonatal period or early infancy. The relationship of duration of circulatory arrest to various developmental outcomes was nonlinear. Developmental scores did not decline until the duration of total DHCA exceeded a threshold of approximately 41 minutes (95% one-sided lower confidence limit of 32 minutes) (74). A universally “safe” duration of total circulatory arrest cannot be determined, however, because of its potential interaction with patient factors, such as age, and a host of other perfusion variables that affect outcomes. In addition to duration of total circulation arrest (74), these include the depth of hypothermia (75), the rate and duration of core cooling (76), acid–base management during core cooling (77,78), and the degree of hemodilution (79).

The level of cerebral blood flow during cardiopulmonary bypass is affected by arterial carbon dioxide tension (PCO_2) (77,80). In the *alpha-stat* strategy of pH management, arterial PCO_2 is not corrected for the patient’s temperature during hypothermic cardiopulmonary bypass. Thus, patients are relatively alkalotic during hypothermia. In contrast, in the *pH-stat* strategy, CO_2 is added to the bypass circuit to maintain a pH of 7.40 at the patient’s hypothermic temperature. Because higher arterial PCO_2 is associated with greater cerebral blood flow, the *pH-stat* strategy may provide better brain protection during the periods of global brain hypoperfusion that occur during use of hypothermic cardiopulmonary bypass techniques (77,78,81).

Hemodilution during hypothermic cardiopulmonary bypass has also been studied with respect to its effects on brain injury during infant heart surgery. At the profoundly low temperatures (15°C to 18°C) used during infant and neonatal cardiac surgery, hypothermia increases the viscosity of blood and red

blood cell aggregation (82), potentially increasing the risk of microvascular occlusion. Hemodilution has been used to counter these risks (83) and has been shown to increase cerebral blood flow (84), but could reduce the oxygen-carrying capacity of blood. Furthermore, because hypothermia induces a leftward shift of oxyhemoglobin dissociation, hemodilution has the potential to limit oxygen delivery to the central nervous system (83). In a randomized single-center clinical trial of hemodilution strategy in infants undergoing reparative open heart surgery using hypothermic bypass techniques, low hematocrit (20%) at the onset of low-flow bypass was shown to be a risk factor for adverse neurodevelopmental outcome, specifically lower PDI score, at age 1 year (79). A subsequent trial showed no differences in neurodevelopmental outcome at 1 year with hemodilution within the range of 25% to 35% (85).

It is likely that factors such as hematocrit, temperature, pH strategy, and duration of circulatory arrest or very reduced flow interact in their effects on the central nervous system (86,87). For example, the reduced oxygen-carrying capacity of a low hematocrit during cardiopulmonary bypass can be compensated for by the use of the *pH stat* strategy, or by increasing flow rate, reducing duration of circulatory arrest, or reducing temperature.

Preoperative Factors and Host Susceptibility

Host susceptibility is likely to affect the response of the central nervous system to cardiopulmonary bypass and perioperative events (88). Preoperative patient characteristics such as low Apgar scores at 5 minutes, younger gestational age, lower birth weight, and other attributes have been independent risk factors for adverse neurodevelopmental outcome in clinical trials (79,89). Furthermore, response to cardiac surgery may be mediated by genetic polymorphisms in the pathways affected by exposure to cardiopulmonary bypass, including inflammation, thrombosis, vascular reactivity, and oxidative stress (90). Indeed, it is most likely that the effects of bypass on individual patients are mediated by many different genetic polymorphisms in the domains of inflammation, coagulation, and response to ischemia/reperfusion injury.

The influence of genetic polymorphisms on postoperative morbidity has been extensively studied among adults undergoing open heart surgery (91–94). For example, among adults, worse postoperative bleeding is more common among those with polymorphisms in genes coding for coagulation proteins and platelet glycoproteins (95), and postoperative thrombotic complications have been associated with gene polymorphisms in fibrinogen and angiotensin-converting enzyme (96). Postoperative stroke has been found to be more common among patients with genetic variants for C-reactive protein (CRP) and interleukin-6 (IL-6) (97).

Gaynor et al. (98) have studied the effect of *APOE* genotype on neurodevelopmental outcomes in infants after cardiac surgery. The *APOE* $\epsilon 2$ allele was an independent risk factor for worse PDI scores in multivariable regression adjusting for preoperative and postoperative covariates. Indeed, children with the *APOE* $\epsilon 2$ allele had PDI scores that were approximately one-half standard deviation (SD) lower than those with other genotypes. Of note, although an IQ deficit of approximately 0.5 SD is unlikely to be clinically significant for an individual child, when it represents a mean decline in a population its implications are substantial (99). The effect of *APOE* genotype was seen across the spectrum of children with and without genetic syndromes. The adverse effect of *APOE* $\epsilon 2$ allele is most likely related to decreased neuroresiliency and impaired neuronal repair after central nervous system injury. Interestingly, this finding underscores that children and adults may differ with respect to the effects of particular genotypes.

In contrast to infants, adults carrying the APOE ϵ 4 allele who undergo open heart surgery have increased levels of biochemical markers of brain injury (100,101) and a greater rate of postoperative cognitive decline (102,103).

Postoperative Factors

Various risk factors for brain injury occur in the postoperative period. Low cardiac output syndrome is common in the first 24 to 48 hours following repair of complex congenital heart disease (104,105). Hemodynamic instability and low cardiac output syndrome may be especially damaging to the vulnerable central nervous system of the neonate who has just undergone cardiac surgery using deep hypothermic cardiopulmonary bypass techniques. Hypoxic-ischemic insult related to hypothermic cardiopulmonary bypass techniques disrupts the integrity of cerebral vasoregulatory systems in the early postoperative period, and autoregulation of cerebral blood flow is impaired (106–109). Persistence of such disturbances in cerebrovascular control renders the brain vulnerable to subsequent insults, such as hypotension or hypoxia. Galli et al. (48) reported that hypotension and hypoxemia are independent risk factors for periventricular leukomalacia, and found such injury to occur in 50% of neonates undergoing open heart surgery.

General measures of postoperative course complexity also have been associated with later neurodevelopmental outcome. In the Boston Circulatory Arrest Study, children with D-TGA with longer ICU and hospital stays during their arterial switch operation scored worse on tests of cognitive function at age 8 years. Indeed, mean IQ scores among those in the first and fourth quartiles of length of stay differed by one-half SD. Similarly, Limperopoulos et al. (4) studied a more diverse population and found that longer ICU and hospital lengths of stay were independent predictors of worse scores at age 1 to 3 years on various developmental measures. The adverse effect of longer hospitalization on neurodevelopmental outcome reflects multiple contributory factors that prolong recovery.

The hormonal milieu after cardiac surgery might influence the central nervous system. For example, sick euthyroid syndrome is common among infants and children following open heart surgery, and the degree of thyroid suppression appears to be greatest after the most complex operations (110–119). Even transiently low thyroid levels may adversely impact brain development. In cohort studies, preterm infants with transiently low thyroid levels in the first weeks of life have been found to have later abnormalities of neurologic and developmental function, including higher risks of cerebral palsy (120) and learning disabilities (121). Furthermore, transient hypothyroxinemia of prematurity has been noted to be an independent risk factor for cerebral white matter damage (120,122). The causes of thyroid hormone suppression after cardiopulmonary bypass, likely multifactorial, may include hypothermia, hemodilution, and use of medications (e.g., corticosteroids, catecholamines, dopamine) or topical iodinated antiseptic solutions (123–126).

The association of longer hospital length of stay and worse neurodevelopmental outcome may also be mediated by the inflammatory response. Inflammation can precipitate autoregulatory disturbance and microvascular ischemia and cause neonatal cerebral white matter damage (127,128). Circulating proinflammatory cytokines and chemokines, induced by the massive inflammatory effects of cardiopulmonary bypass and subsequently by postoperative events, could be associated with late brain structural and functional abnormalities.

In contrast to the multitude of studies on the effects of intraoperative management strategies, few prospective trials have tested the efficacy of interventions related to postoperative risk factors on later neurodevelopmental outcome.

OTHER CAUSES OF NEUROLOGIC MORBIDITY

Cardiac catheterization in children has been associated with neurologic complications at a reported incidence of 0.38%; the most frequent sequelae are seizures and stroke (129). Similar to cardiac surgery, cardiac catheterization may be associated with cerebral embolism or hypoxic/ischemic injury secondary to hypoperfusion. In addition, contrast toxicity may be a cause of seizures after cardiac catheterization (130). Catheter interventions may increase the associated risk of cerebrovascular injury for some patient groups. McQuillen et al. (131) performed brain MRI on newborns with D-TGA prior to cardiac surgery and found that 12 of 19 patients who required balloon atrial septostomy, compared to 0 of 10 newborns who did not require balloon atrial septostomy, had evidence of focal or multifocal brain injury. However, other groups have not found balloon atrial septostomy to be associated either with evidence of cerebrovascular accident by MRI (132,133) or with clinical stroke (134) in children with D-TGA.

Although procedures such as open heart surgery or cardiac catheterization are most commonly associated with embolic stroke in children with congenital heart disease, embolic strokes can also occur from intracardiac thrombi that form in the setting of arrhythmia (e.g., atrial fibrillation), poor left ventricular function, and left-sided prosthetic valves. Furthermore, paradoxical emboli may travel from the systemic circulation (e.g., systemic veins, right-sided cardiac structures, or venous catheters) through an intracardiac communication to the brain. Patients with venous hypertension and polycythemia are at increased risk for cerebral venous thrombosis. Risk of cerebrovascular accidents may also increase in the setting of relative anemia in patients with cyanotic heart disease and increased blood viscosity (135).

Infections in the heart or brain may cause neurologic morbidity among children with congenital heart disease. Most common among these is the occurrence of infective endocarditis, with its risk of septic or nonseptic emboli and of mycotic aneurysms (136, 137, 142). Even in the current era, congenital heart disease is the most common predisposing cause of brain abscess (138). Brain abscess is especially common in individuals with cyanotic heart disease, with the incidence inversely related to oxygen saturation (139–144). Because of the high morbidity and mortality of brain abscess, this diagnosis should be pursued with contrast-enhanced computed tomography or brain MRI in patients with cyanotic heart disease and suggestive clinical features, such as headache, seizures, fever, and findings on neurologic examination.

LONG-TERM NEURODEVELOPMENTAL OUTCOME

Compared with the normal population, children who have undergone repair or palliation of congenital heart defects have significantly lower IQ scores, inferior achievement testing, and worse gross and fine motor function and coordination. Many require special services because of their higher frequencies of learning disabilities and of speech, language, and behavioral abnormalities (4,72,145–150). Visual-spatial skills are an area of relative weakness among children with congenital heart disease (148–151). On a measure of functional independence 1 to 3 years after surgery, Limperopoulos et al. (148) reported that only 21% of congenital heart disease survivors scored within the age-appropriate range, 40% had difficulty performing activities of daily living, and 53% had poor socialization skills. Compared with children with acyanotic heart disease or no heart disease, children with cyanotic congenital heart

disease have lower IQs and poorer perceptual and gross motor function (152–154). Furthermore, longer duration of significant cyanosis is associated with a greater decline in cognitive ability (154–160). In general, outcomes after repair of simple lesions, such as atrial septal defects, are similar to those in the normal population, whereas developmental outcomes appear to be worse after biventricular repair of more complex lesions (5,146,159,160–163), though the specific causative factors and the role of cardiopulmonary bypass remain unclear (160). Adverse developmental outcome is most common among those with various forms of single ventricle (72,145,166).

Outcomes in Diagnostic Groups

Congenital heart disease comprises rare and diverse disorders, and most studies of development in children with congenital heart disease include patients with heterogeneous lesions. However, children in a few diagnostic groups have been studied in greater detail, and these are briefly reviewed.

D-Transposition of the Great Arteries

Patients with D-TGA have been studied in great detail in the Boston Circulatory Arrest Study, a randomized trial of predominant total circulatory arrest versus low-flow cardiopulmonary bypass for vital organ support during the arterial switch operation in the neonatal period and early infancy. Patients were followed perioperatively and at ages 1, 4, 8, and 16 years. (89,104,147,164–168,186). By age 1 year, 23% of children had a possible or definite abnormality on brain MRI examination, although the frequency was not related to treatment assignment or duration of circulatory arrest. MRI abnormalities were diffuse in 16 children, focal/multifocal in 20, and developmental (incidental) in 3. At 2.5 years of age, the circulatory arrest group had slower expressive language development and, at 4 years, had lower fine and gross motor scores as well as more speech/language abnormalities and oromotor apraxia. Children in both treatment groups, however, had higher rates of neurodevelopmental problems than would be expected in a normal population. At age 4 years, for instance, the mean Full-Scale IQ was approximately 0.5 SD below the expected population mean; both groups had marked difficulties on tests of expressive language, visual-spatial, and visual-motor skills; and 24% met diagnostic criteria for oromotor apraxia (147).

By age 8 years, when the children had begun primary school and were being challenged to acquire academic skills (e.g., reading, mathematics), the practical implications of the deficits noted at earlier evaluations could be determined with greater certainty (90). Performance in both motor function and visual-spatial skills was especially weak. Other areas of weakness included working memory, hypothesis generation and testing, vigilance and sustained attention, and higher-order language skills. These problem areas contributed to difficulty with executive function, that is, the ability to organize, implement, and modify plans (169). As a group, the cohort had difficulty integrating details into a coherent whole and in higher-order abstract thinking. For example, most children could read individual words without undue difficulty, but many had difficulty reading connected discourse for meaning. Similarly, the children scored well in basic arithmetic but had difficulty solving math problems. The neurodevelopmental characteristics of children with D-TGA were typical of non-verbal learning disability (170).

Other investigators have also reported that children with D-TGA have neurodevelopmental performance below that in the normative population. Ellerbeck et al. (151) reported that children with D-TGA were more likely to have abnormal neurologic examination findings and learning disabilities

than either the general population or their siblings. Similarly, Karl et al. (171) found that, on later follow-up, patients with D-TGA who underwent the arterial switch operation had a higher likelihood of abnormalities on neurologic exam, lower IQ, more motor impairment, and more speech and expressive language problems than a normal control group. In a Congenital Heart Surgeon's Society study of children who underwent repair of D-TGA between 1985 and 1988 at 24 centers, parents reported learning disabilities in 31% of children, behavioral disorders in 13%, hyperactivity in 12%, and cerebral palsy in 3%. Risk factors for adverse outcomes included institution, longer circulatory arrest time, postoperative seizures, and use of a repair other than the arterial switch operation (172).

Tetralogy of Fallot

Although TOF is one of the most common forms of congenital heart disease, data on associated neurodevelopmental deficits are more limited than for D-TGA. Shampaine et al. (173) studied, at a mean age of 30 years, 21 patients with TOF who underwent surgical repair at a mean age of 8.7 years. Their mean IQ in adulthood was 93.4, with an SD of 15.6. Personality assessment revealed reduced scores on adaptability and leadership scales, as well as higher scores on harm avoidance. The patients were described, in summary, as low average in intellectual development, and characterized by anxiety and dependency (173). Other early studies by Ferencz (174) and Garson et al. (175) also suggested increased psychosocial morbidity among TOF patients. In more recent studies, patients with TOF have been included in samples with heterogeneous forms of congenital heart disease (176). In one study in which analyses were stratified, the TOF group was reported to have a mean IQ of 100 (177). The validity of this observation is limited, however, by the exclusion from the study sample of "... children who had any postoperative complication likely to affect development ... [and] children known to have any preoperative intellectual handicaps." Clarkson et al. (65) found that the mean IQ of 17 patients with TOF (88.5) was lower than the mean IQs of any of the other diagnosis groups (ventricular septal defect, D-TGA, total anomalous pulmonary venous return, atrioventricular septal defect, other), which ranged from 90.6 to 102.4. Neurodevelopmental outcome of patients with TOF is thought to be influenced by the presence of an underlying genetic abnormality (e.g., 22q11 microdeletion, Alagille syndrome).

Single Ventricle

Children with single ventricle are at highest risk for adverse developmental sequelae. This group often has prolonged cyanosis, congestive heart failure, multiple cardiac catheterizations, and a series of operations culminating with Fontan palliation. They also are likely to have disturbances of cerebral flow in utero, cerebral dysgenesis, and genetic or associated congenital abnormalities. Neonates with HLHS and other duct-dependent forms of single ventricle may have unstable preoperative hemodynamics and lower cerebral oxygen saturation levels than patients with other forms of congenital heart disease. In addition, infants with HLHS and other forms of single right ventricle undergoing the Norwood procedure have relatively long periods of DHCA and are especially subject to postoperative hemodynamic instability.

In a small series, Uzark et al. (64) studied 32 children following the Fontan procedure. Mean IQ was 97.5 ± 12.1 , and visual motor integration was a particular area of weakness. Use of total circulatory arrest as part of the Norwood procedure tended to be a risk factor for adverse outcome. Wernovsky et al. (145) measured ability and achievement in

a cohort of geographically selected survivors whose Fontan procedure was performed in the 1970s and 1980s. Subjects were a median of 11 years of age at testing and 6 years after surgery. Median Full-Scale IQ was 95.7 ± 17.4 , significantly lower than that in the normal population; 8% of patients scored in the mentally retarded range (<70). In multivariable analyses adjusting for social class, lower IQ was associated with the use of circulatory arrest and with the anatomic diagnosis of HLHS or "Other" complex forms of single ventricle, and marginally with prior placement of a pulmonary artery band. Mean composite achievement score was 91.6 ± 15.4 , much worse than normal and relatively worse than IQ scores, suggesting the presence of learning disabilities. Independent risk factors for worse achievement included the diagnosis of HLHS and "Other" complex single ventricle, or prior use of total circulatory arrest, as well as with reoperation using cardiopulmonary bypass within 30 days after the Fontan procedure. In a more contemporary series of neurodevelopmental outcome after the Fontan procedure, Goldberg et al. (178) found a mean Full-Scale IQ score of 101.4 ± 5.4 . Those with HLHS scored significantly lower (93.8 ± 7.3) than those without HLHS, and additional risk factors for worse neurodevelopmental outcome included lower socioeconomic status, longer duration of circulatory arrest, and occurrence of perioperative seizures.

Indeed, children with HLHS appear to have the highest risk of neurodevelopmental disabilities of any form of congenital heart disease (72,73,178–182). Mahle et al. (72) performed neurocognitive testing on a local group of school-aged survivors of Fontan procedure repaired at Children's Hospital of Philadelphia before 1992. Among 28 children, 18% were mentally retarded, 14% had learning disabilities, 17% had cerebral palsy, and 13% had microcephaly; most children had attention deficit and hyperactivity disorder. Risk factors for worse neurodevelopmental outcome included seizures (lower Full-Scale, Verbal, and Performance IQ scores) and longer bypass time (Performance IQ and achievement in math and reading). Neither social class nor duration of total circulatory arrest was an independent risk factor in this small series, perhaps because the variation attributable to socioeconomic factors was overwhelmed by other medical factors, and the duration of circulatory arrest had a narrow range. The Single Ventricle Reconstruction Trial, conducted through the Pediatric Heart Network, was designed primarily to compare outcomes of children with HLHS randomized to a right ventricle to pulmonary artery shunt to outcomes of participants randomized to a Blalock-Thomas-Taussig shunt (181). Long-term follow-up of this large multicenter cohort enrolled in the Single Ventricle Reconstruction Trial promises to lead to further insights about factors associated with impaired neurodevelopmental outcomes for this high-risk patient group.

Children with HLHS may also be treated with a primary cardiac transplant strategy. Ikle et al. (182) studied developmental outcome of HLHS patients undergoing cardiac transplantation as a primary management strategy. Median Full-Scale IQ was almost 1 SD below average in the normal population. A more recent prospective, multicenter study compared the neurodevelopmental outcomes of school-aged children (mean age 12.4 ± 2.5 years) with HLHS managed by primary heart transplantation compared with staged palliation (73). Among the 47 children who completed testing, 26 had undergone the Norwood procedure and 21, cardiac transplantation. The mean Full-Scale IQ for the cohort was 1 SD below normal (i.e., 86 ± 14), and surgical strategy was not significantly associated with any developmental outcome. As has been noted in other studies, a prolonged initial hospitalization stay was a risk factor for adverse neurodevelopmental outcomes.

Psychosocial Function and Academic Ability and Achievement

Quality of life has been studied in several populations of children and adolescents with congenital heart disease (183–186). Using the Child Health Questionnaire (CHQ)-50, parents of 8-year-old children with D-TGA in the Boston Circulatory Arrest Study rated their children similarly to parents of normative samples with respect to overall physical and psychosocial health (186). However, within the D-TGA group, measures of academic ability and achievement emerged as the most significant correlates of psychosocial functioning. Specifically, worse Psychosocial Summary scores were associated with lower Full-Scale, Verbal, and Performance IQ scores, as well as with worse academic achievement. Indeed, psychosocial health in this population was lower than in patients with juvenile rheumatoid arthritis or asthma, but higher than those among children with attention deficit hyperactivity disorder (ADHD). These data are consistent with the association of learning disabilities with psychosocial dysfunction in the general population (187).

Culbert et al. (188) studied 306 of 708 adolescents who underwent repair of D-TGA between 1985 and 1988 at 24 centers and included children who had undergone arterial switch, atrial switch, and Rastelli repairs. The CHQ-87 instrument was completed by each child. Patients with D-TGA scored higher than the normative population except in self-esteem. Use of the arterial switch operation was associated with higher scores than atrial or Rastelli repairs. Thus, adolescents with D-TGA in this series did not view themselves in a fashion suggesting low psychosocial functioning. Of note, parents of these adolescents did not complete a general health status instrument in this study.

General health status was also assessed by parents of 6- to 18-year-old patients who had undergone the Fontan operation using the CHQ-50 instrument (189,190). Both physical and psychosocial health scores were lower in Fontan patients than among normal children or other populations of cardiac children except for those with pacemakers and automatic internal defibrillators. It seems likely that low scores in the Fontan group are related to their many medical morbidities and lower cognitive function. Worse psychosocial health was associated with the parent's report of current presence of problems with behavior, learning, anxiety, attention, and depression, as well as with lower family income.

The recent development of quality of life measures that are cardiac specific (191,192) will be valuable as we aim to identify modifiable variables to improve quality of life for children with congenital heart disease. Using these measures, children with more severe congenital heart disease have rated their physical and psychosocial quality of life lower than children with milder heart disease (191,192).

Mental Health

Rates of psychosocial dysfunction, particularly depression and panic disorder, have been reported to be elevated in long-term follow-up studies of patients with congenital heart disease (193–195). Many adolescents meet some but not all DSM (*Diagnostic and Statistical Manual of Mental Disorders*) criteria (196–198), and many adolescents with congenital heart disease report low self-esteem (199). These data are consistent with reports that American youth who have a chronic physical illness bear a disproportionate burden of psychiatric comorbidities, particularly depression (200–204). Among adolescents with other forms of physical illness, depression has been associated with higher health care utilization, poorer medical outcome, heightened functional impairment, decreased quality of life, and increased mortality (205–208).

CONCLUSION

In summary, neurologic and developmental sequelae have a major impact on the lives of children with congenital heart disease and their families, sometimes eclipsing the heart disease itself. Children with most diagnoses requiring open heart surgery should be presumed to be at risk, and pediatric cardiologists should incorporate neurodevelopmental surveillance in their routine care of the child with congenital heart disease. Because cognitive disabilities and poor school performance are associated with lower psychosocial health and self-esteem, appropriate interventions should be initiated promptly as problems are detected. In addition, families should be counseled to anticipate issues that may arise in school performance. Recognizing the significant risk to development associated with complex congenital heart disease, there is growing enthusiasm for routine screening for developmental delays and behavioral abnormalities to provide earlier recognition of neurocognitive problems and therefore earlier referral for appropriate interventions. In the future, it is hoped that the prevalence of neurologic and developmental disabilities may be further diminished through advances in engineering and bioengineering, pharmacogenomics, and perioperative care.

Hematologic Aspects of Pediatric and Adolescent Heart Disease: Bleeding, Clotting, and Blood Component Abnormalities

Therese M. Giglia ■ Char Witmer

The cardiovascular system is both the conduit and the propeller of the circulating blood, and as such, a mandatory codependence exists between these two organ systems. As expected, perturbations in one system result in alterations in the other and vice versa. The purpose of this chapter is to describe the cardiovascular effects of hematologic derangements on the normal heart as well as the hematologic problems seen in children and adolescents with congenital and acquired heart disease. The chapter begins with an overview of basic principles of hematology in the developing child and progresses to discussions of abnormalities in individual blood components and bleeding and how each affects the normal heart as well as the heart of the child and adolescent with congenital and acquired heart disease. Since thrombosis is becoming more commonly recognized as a major source of morbidity and at times mortality in children with heart disease, the chapter ends with a detailed discussion of thrombosis in pediatric heart disease including a description of anticoagulants, antiplatelet agents, and thrombolytic therapy commonly used in children with these disorders.

BASIC PRINCIPLES OF HEMATOLOGY

Red Blood Cells

Red blood cells (RBC) are nonnucleated biconcave discs whose major cellular component is hemoglobin (Hb), an oxygen transport protein. Erythropoietin, a hematopoietic growth factor produced in the kidney, is the major regulator of red cell production. A normal red cell life span is approximately 120 days. Normal developmental factors influence Hb values in children including age, gender, and sexual maturity necessitating the need for age-appropriate reference values.

Hb production begins early in gestation and undergoes a series of transitions. Hb is formed by two pairs of identical subunits called globin chains. Fetal erythropoiesis consists of an orderly evolution through a series of different Hbs. All forms of Hb are made up of a combination of two α -like globin proteins (α or ξ) and two β -like globin proteins (β , δ , γ , or ϵ). In the embryo, the predominant Hbs include Gower 1 ($\xi_2\epsilon_2$), Gower 2 ($\alpha_2\epsilon_2$), and Portland ($\xi_2\gamma_2$). In the fetus, there is a transition to fetal Hb ($\alpha_2\gamma_2$). After birth, there is a final switch to adult Hb ($\alpha_2\beta_2$).

At birth, neonates have a mean Hb of 15.9 g/dL (± 1.86) and an elevated mean corpuscular volume (MCV) of 110 fL (± 5) (1). After birth, red cell production quickly decreases likely

secondary to the abrupt increase in oxygen concentration. The half-life of neonatal red cells is shorter (average 23.3 days) than in adults and is even shorter in premature infants (average 16.6 days) (2). The Hb naturally decreases over the first 2 to 3 months of life (physiologic nadir) and then slowly increases in the fourth to sixth month of life. Throughout childhood, there is a mild increase in the mean Hb. In males during puberty, as the Tanner stage increases, the Hb increases. There is no relationship between Hb and Tanner stage in females.

White Blood Cells

White blood cells (WBC) play an integral role in the immune system. There are five types of WBC including neutrophils, eosinophils, basophils, lymphocytes, and macrophages/monocytes. Individual WBC percentages have limited clinical utility; instead, absolute counts should always be considered. The WBC reference range will vary with age. In general, newborns have a higher total WBC (mean 18.1 k/ μ L) that will quickly decrease over the first week of life. Lymphocyte predominance is seen from 2 weeks to approximately 5 years of age, then neutrophils become predominant.

Hemostasis

Platelets are small anucleated cell particles that are made in the bone marrow via fragmentation of megakaryocytes; production is mediated via thrombopoietin. Platelets circulate for approximately 7 to 10 days and are subsequently removed via the reticuloendothelial system. By 18 weeks of gestation, the plasma platelet concentration reaches the adult range of 150 to 450 k/ μ L. At birth, neonates have the same platelet count range and volume as adults. Data regarding platelet function in neonates demonstrate hyporeactivity to some agonists and hyperreactivity to others (1). Platelets play an integral role in hemostasis.

Hemostasis refers to the coordinated process that stops bleeding at the site of vascular injury through the formation of an impermeable platelet and fibrin plug. Hemostasis is achieved through the following three main mechanisms:

- Vascular constriction
- Primary platelet plug formation (primary hemostasis)
- Clot propagation through fibrin formation (secondary hemostasis)

Vascular constriction decreases blood flow at the site of injury. Platelets adhere to the exposed subendothelium, through

von Willebrand factor (vWF) tethering, forming an initial platelet plug. Simultaneously, coagulation is initiated by the exposure of tissue factor. Tissue factor binds and activates FVII that activates the coagulation cascade, resulting in a small thrombin burst. This small thrombin burst stimulates further platelet activation and the activation of coagulation on the platelet surface. On this increased platelet surface, a large amount of thrombin is formed that is sufficient to convert fibrinogen to fibrin leading to stable clot formation. To limit clot formation at the site of injury, activated procoagulant proteins are inhibited by anticoagulant proteins (protein C, S, antithrombin, thrombomodulin, heparin cofactor II, and tissue factor pathway inhibitor). Clot degradation is initiated by the fibrinolytic system (plasminogen, tissue plasminogen activator, and urokinase plasminogen activator). This is a finely balanced system, and a derangement at any level can result in a tendency for bleeding or a prothrombotic state.

In the neonate, these hemostatic processes are in place but in different concentrations than adults. In normal postnatal development, many values normalize by 6 months of age, although changes can still be seen throughout childhood (3,4). Understanding the difference in neonatal values is imperative when interpreting coagulation studies to ensure the correct diagnosis of either a bleeding or clotting disorder. It also has direct implications for the use of specific hemostatic interventions in a neonate (i.e., unfractionated or low molecular weight heparin (LMWH) therapy).

Coagulation proteins do not cross the placenta and are independently synthesized by the fetus; most are present by 10 weeks of gestation and gradually increase with gestational age (5,6). In a neonate, the following procoagulant proteins are decreased including the vitamin K–dependent factors (II, VII, IX, and X) and the contact pathway factors (XI, XII, prekallikrein, and high molecular weight kininogen) (4,6,7). This results in a prolonged prothrombin time (PT) and partial thromboplastin time (PTT) when compared to normal adult values. Conversely, neonates have increased plasma vWF levels and elevated levels of circulating ultra-large von Willebrand multimers (8,9). Similar to the procoagulant factors, the inhibitors of coagulation are also decreased. The anticoagulant proteins including protein C, S, antithrombin, heparin cofactor II, and tissue factor pathway inhibitor are decreased, resulting in a slower rate of thrombin inhibition (4,6,7,10). The fibrinolytic system is also depressed secondary to a unique neonatal glycoform of plasminogen that is inefficiently converted to plasmin (11). Neonates will have markedly elevated D-dimer values at birth lasting up to 3 days (7,10).

HEMATOLOGIC DISORDERS

Special Consideration of Hematologic Disorders in Congenital Heart Disease

Adolescents and children with congenital and acquired heart disease are at increased risk for hematologic abnormalities including red cell anomalies, bleeding, and thrombosis. The following sections discuss individual hematologic disorders describing the effects on the normal heart and in addition paying attention to particular concerns regarding the child and adolescent with congenital heart disease (CHD).

Disorders of Red Blood Cells

Anemia

Anemia is defined as a decrease in Hb that is two standard deviations below the mean value for age. Physiologically, anemia can be divided into three main categories: decreased or ineffective RBC production, increased RBC destruction, or blood loss. The etiology of an anemia can be determined using a morphologic approach based on the red cell MCV. The initial approach to anemia should include a thorough history, physical exam, complete blood count (CBC) with differential, reticulocyte count, and review of the peripheral smear.

The differential for a *microcytic anemia* is rather narrow and includes acquired and congenital causes. The most common acquired cause in pediatrics is iron deficiency. Premature infants are at increased risk for iron deficiency secondary to decreased in utero iron absorption, decreased birth weight, and concurrent anemia. Toddlers commonly have dietary-induced iron deficiency when there is excess milk intake combined with poor solid food intake. The congenital causes for a microcytic anemia include β - or α -thalassemia trait, other forms of thalassemia, sickle cell combined with thalassemia, or anemia of chronic disease. Table 75.1 provides a summary of laboratory values to help differentiate between the common causes of a microcytic anemia. An Hb electrophoresis helps in diagnosing other forms of thalassemia and sickle cell disease (SCD).

A *normocytic anemia* has a much broader differential than a microcytic anemia. Figure 75.1 provides a flow diagram for the approach to a normocytic anemia. The reticulocyte count should be used to further classify the anemia into two broad categories of increased or decreased red cell turnover.

TABLE 75.1 Laboratory Evaluation for a Microcytic Anemia

Test	Iron Deficiency	Anemia of Chronic Disease	α -Thalassemia Trait	β -Thalassemia Trait
Serum ferritin	↓Low	Normal to ↑high	Normal	Normal
Serum iron	↓Low	↓Low	Normal	Normal
TIBC	↑High	↓Low	Normal	Normal
Transferrin saturation	↓Low	↓Low	Normal	Normal
MCV	↓Microcytic	Micro- or normocytic	↓Microcytic	↓Microcytic
RDW	↑Increased	↑Increased	Normal	Normal
Hemoglobin electrophoresis	Normal	Normal	Normal *Hemoglobin Barts on newborn screen	↑Elevated hemoglobin A2 and/or F

TIBC, total iron binding capacity; MCV, mean corpuscular volume; RDW, red cell distribution width.

Figure 75.1. The differential for a normocytic anemia.

The reticulocyte count needs to be adjusted for the degree of anemia to determine if it is truly elevated. A reticulocyte index (RI) can be calculated as

$$\frac{\text{Patient's hematocrit}}{\text{Normal hematocrit}} \times \text{Patient's reticulocyte count.}$$

An RI > 3 indicates increased red cell turnover and an RI < 3 indicates decreased red cell turnover. In patients with an elevated RI, it is important to differentiate between bleeding versus red cell destruction (*hemolysis*). Laboratory markers of hemolysis include an increased lactate dehydrogenase (LDH), elevated indirect bilirubin, elevated aspartate aminotransferase (AST) with a concomitant normal alanine transaminase (ALT), or a decreased haptoglobin.

Patients with congenital or acquired are at increased risk for developing an *acquired hemolytic anemia* from an increase in shear forces most commonly seen in patients with prosthetic valves. These patients will develop an anemia with an elevated RI. Review of the peripheral smear will show red cell fragments that will have evidence of intravascular hemolysis with a decreased haptoglobin, increased LDH, and hemoglobinuria. Other markers of hemolysis including indirect bilirubin or AST may or may not be elevated.

Macrocytic anemia is much less common in pediatrics. The differential includes vitamin B₁₂ or folate deficiency, hypothyroidism, bone marrow failure, significant reticulocytosis, liver disease, or medications. Common medications that can increase the MCV include hydroxyurea, zidovudine, or chemotherapeutic agents. In the neonatal period, infants normally have an increased MCV. In Down syndrome, an increased MCV is common in up to two-thirds of patients (12).

Anemia and RBC transfusion in children and adolescents with CHD: Since children and adolescents with cyanotic heart disease have higher Hb levels commensurate with their desaturation and higher than age-matched controls without cyanotic heart disease, assessment of anemia is more challenging. Recognition of this discrepancy is imperative to being able to diagnose anemia in patients with CHD. Paying attention to a particular patient's baseline values and a change over time will be more informative than age-matched normal values.

Children with cyanotic defects are commonly transfused to an Hb >14 g/dL especially postoperatively or during periods of hemodynamic instability to increase their oxygen-carrying

capacity and optimize oxygen delivery. The rationale of this strategy is that a compromised cyanotic patient has limited ability to increase cardiac output to compensate for a low systemic oxygen delivery (13–15). Although a common practice, there is a paucity of data on the optimal Hb concentration and transfusion strategies in these patients. A recent, single-center, prospective, randomized, controlled clinical trial compared a restrictive Hb strategy (mean Hb 11 g/dL, mean RBC transfusions 0.43) to a liberal strategy (mean Hb 13.9 g/dL, mean RBC transfusions 2.1) in children during the first 48 hours after bidirectional cavopulmonary or Fontan operation (16). No differences were found in mean or peak arterial lactate, arteriovenous or arteriocerebral oxygen content, or clinical outcomes. This question warrants further investigation.

Red Blood Cell Disorders with Particular Cardiac Manifestations

SCD and thalassemia are two congenital red cell disorders with well-defined cardiovascular complications. SCD is a group of *inherited hemoglobinopathies* that are the result of abnormal Hb production. It is a multisystem disease characterized by a chronic hemolytic anemia and vaso-occlusive complications resulting in episodes of acute illness and a chronic progression to end-organ damage. SCD is an autosomal recessive condition. The most common form of SCD is homozygous SS. Other variants of SCD are the result of other Hb variants combined with Hb S (i.e., SC, S-β⁰ thalassemia or S-β⁺ thalassemia). More than 100,000 Americans are affected with SCD. The carrier rate in African Americans is approximately 8% (1 in 12).

In Hb S, an amino acid substitution in the β-globin gene from glutamic acid to valine ultimately leads to the polymerization of Hb S molecules, causing the red cell "sickling" effect with resultant vascular occlusion and hemolytic anemia. SCD was once seen as a disease where the morbidity and mortality were directly related to vascular occlusion but it is now evident that chronic hemolysis significantly contributes to the development of endothelial dysfunction and vasculopathy. With intravascular hemolysis, there is a release of free Hb that generates reactive oxygen species that are potent scavengers of nitric oxide (17). There is also a release of arginase that decreases nitric oxide bioavailability. Nitric oxide has several key roles in endothelial function including as a regulator of vasodilator tone and inhibitor of platelet and hemostatic

activation (18–20). SCD confers a state of nitric oxide resistance, and human and animal studies have provided evidence that a reduction in nitric oxide is associated with vasoconstriction, decreased blood flow, platelet activation, and end-organ injury (21).

Cardiac involvement in SCD is quite common and is primarily the result of a chronic anemia with a compensatory increased cardiac output. In general, the heart is usually enlarged and a systolic ejection murmur is found in most patients. Fifty percent of pediatric patients will have electrocardiographic findings of left ventricular (LV) hypertrophy (22). The steady-state blood pressure in patients with SCD is lower than that in age-, race-, and gender-matched controls (23). This finding is likely related to the steady-state anemia as well as renal losses of sodium and water. While vaso-occlusion is a common occurrence in SCD, myocardial infarction is quite rare although infarction of LV papillary muscles with mitral regurgitation has been reported (22,24,25). Autopsy studies show that atherosclerosis is also uncommon in this patient population (24).

Pulmonary hypertension (PH) is a common complication in adult patients with SCD with a reported prevalence of 6% to 32% and has been associated with significant morbidity and mortality (26,27). Studies with a higher prevalence of PH only used echocardiographic assessments of pulmonary artery systolic pressure with a cutoff tricuspid regurgitant (TR) jet velocity of 2.5 m/s. A recent prospective study in adult patients with SCD utilized right heart catheterization to confirm the echocardiographic findings. They reported a prevalence of elevated TR jet velocity of 27% (consistent with prior studies) but right heart catheterization confirmed PH in only 6% of subjects (27). Studies addressing PH in pediatric patients with SCD are limited but have not demonstrated the increased morbidity and mortality seen in adults (28–32). The prevalence of elevated TR velocities is similar in children as in adults; however, the significance of the findings and implications for prognosis remain unclear. Further pediatric studies that follow patients into adulthood are required.

The etiology of PH in patients with SCD is likely multifactorial. Hemolysis is believed to play a key role in the development of PH through endothelial dysfunction. Other chronic hemolytic disorders have an increased incidence of PH including thalassemia, hereditary spherocytosis, and paroxysmal nocturnal hemoglobinuria. Other contributing factors in SCD may include chronic hypoxia, chronic thromboembolism, in situ thrombosis, parenchymal and vascular injury from sequestration of sickled erythrocytes, chronic liver disease, iron overload, and asplenia (33).

Patients with SCD who undergo surgery are at increased risk for morbidity and mortality (34–36). Specific morbidities include acute chest syndrome, SCD, cerebrovascular accidents, and infections. These risks are likely secondary to the underlying anemia from SCD, a propensity for microvasculature occlusion from sickled red cells, and asplenia. Improved outcomes have been reported in patients who received preoperative transfusions to a goal Hb level of 10 g/dL (which decreases the percent S and improves the patient's baseline anemia), hydration, and aggressive intra- and postoperative monitoring (37,38). The patient's hemodynamic status, that is, the effect of volume overload on a left-to-right shunt or ventricular dysfunction, will need to be considered. If a patient with SCD requires cardiac surgery or prolonged sedation for a cardiac procedure, a pediatric hematologist should be involved to work with the cardiologist/intensivist and cardiac anesthesiologist to determine the appropriate pre- and postoperative management.

Thalassemia syndromes are a group of inherited anemias resulting from defects in the production of Hb. Thalassemia is classified according to the globin chain that is underproduced,

either α (α -thalassemia) or β (β -thalassemia) globin. A decrease in the production of either an α - or β -globin chain results in an excess of free globin chains that precipitate in the red cell and cause RBC membrane damage. The end result is anemia from RBC hemolysis and ineffective erythropoiesis in the bone marrow. α -Thalassemia is more commonly found in Southeast Asia, whereas β -thalassemia is more common in Mediterranean countries.

There are two α -globin genes located on chromosome 16. α -Thalassemias are usually the result of gene deletions. The severity of disease is related to the number of gene deletions present. One gene deletion is termed a silent carrier and has no hematologic manifestations. A two-gene deletion is termed α -thalassemia trait; the patient has a mild microcytic hypochromic anemia but is otherwise well with a normal Hb electrophoresis. A three-gene deletion results in Hb H disease. Hb H is composed of tetramers of β -globin. Patients with Hb H disease have a moderate microcytic hemolytic anemia and are not transfusion dependent. The Hb electrophoresis will demonstrate the presence of Hb H. The presence of a four-gene deletion is termed hydrops fetalis and results in severe anemia in the fetus with intrauterine death.

There is one β -globin gene located on chromosome 11. Point mutations are the most common type of genetic mutation in β -thalassemia. β -Thalassemia trait occurs when only one gene is affected, resulting in a mild microcytic anemia. Hb electrophoresis shows increased Hb A2 and/or Hb F levels. In contrast, the inheritance of two affected β -globin genes results in a broad spectrum of clinical disease. Severity is determined by the residual amount of β -globin synthesis. The clinical phenotype ranges from transfusion dependence (β -thalassemia major) to a moderate anemia that does not necessitate chronic transfusions (β -thalassemia intermedia).

Treatment of β -thalassemia major consists of either lifelong chronic red cell transfusions or bone marrow transplant. Chronic red cell transfusions correct the anemia and suppress ineffective erythropoiesis. Transfusions are typically given every 3 to 4 weeks with target nadir Hb of 9 to 10 g/dL. Unfortunately, a direct consequence of chronic transfusions is iron overload with excessive iron deposition in the liver, heart, and endocrine organs.

Currently, heart failure is the most common cause of death in patients with β -thalassemia major. Most of these deaths are attributable to cardiac iron overload (39,40). The most common cardiac abnormality in patients with heart failure from iron overload is a biventricular dilated cardiomyopathy, and severe right ventricular cardiomyopathy is evident in advanced disease (41). Iron deposition is greatest in the ventricular walls and less in the atria and the conduction system. Cardiomyocytes are also sensitive to oxidative damage from non-transferrin-bound iron. Pericarditis was common prior to the use of chelation therapy but appears to be decreasing in frequency (42). Paroxysmal atrial fibrillation is common and is typically associated with myocardial dysfunction; restoration of sinus rhythm does not usually reverse the cardiomyopathy (42). Currently, iron loading in the heart can be measured using MRI T2* technology, >20 ms indicates no significant iron loading, 10 to 19 ms indicates mild-to-moderate iron loading, and <10 ms indicates severe cardiac iron loading (43).

Iron overload is currently treated with chelation. First-line chelators currently in use in the United States include deferoxamine, which is given as a 12-hour infusion intravenously or subcutaneously or deferasirox, an oral medication given once daily. Recently, deferiprone was approved as a second-line oral chelator in the United States. An escalation in chelation therapy is imperative for patients with significant cardiac iron loading. Recent studies have demonstrated that deferiprone in combination with an additional chelator has improved cardiac

iron removal versus monotherapy (44–46). Patients can experience a reversal of the iron-induced cardiomyopathy with intensive chelation (42).

Polycythemia

Polycythemia is defined as an increase in red cell volume, especially the Hb or hematocrit is two standard deviations above the mean value for age. Polycythemia can be classified by the response of erythroid progenitors to cytokines (i.e., erythropoietin) (47). In primary polycythemia, erythroid progenitors exhibit an excessive response to cytokines secondary to an inherited or acquired genetic mutation (i.e., polycythemia vera or erythropoietin receptor mutations). Secondary polycythemia is characterized by a normal response of the erythroid progenitors to elevated levels of cytokines. Secondary polycythemia is usually the result of a physiologic response to chronic hypoxia (i.e., cyanotic CHD or sleep apnea), autonomous erythropoietin production (tumor secretion), or exogenous erythropoietin administration. Rarely, secondary polycythemia can be due to Hb variants with an altered affinity for oxygen or genetic mutations that result in disordered hypoxic sensing.

Disorders of White Blood Cells

Two genetic disorders, Barth Syndrome and 22q11.2 deletion syndrome, have both CHD and white cell disorders. Barth syndrome is an X-linked recessive mitochondrial disorder that is characterized by a dilated cardiomyopathy with endocardial fibroelastosis, skeletal myopathy, growth retardation, neutropenia, and organic aciduria (48,49). It is secondary to mutations in the TAZ gene that is responsible for remodeling the mitochondrial phospholipid: cardiolipin (50). The etiology of neutropenia in Barth syndrome is unclear at this time. Treatment can include granulocyte colony-stimulating factor to prevent severe neutropenia. Chromosome 22q11.2 deletion syndrome encompasses a heterogeneous group of disorders. The most common phenotypic features include conotruncal cardiac malformations, immunologic dysfunction, developmental delay, and palate deformities (51). Immunologic dysfunction is the result of thymic aplasia or hypoplasia resulting in a variable T-cell deficiency with a resultant increase in infections and autoimmune disease (52). Decreased regulatory T cells may play a role in the increased incidence of autoimmune disorders (52,53). Autoimmune disease can include acquired cytopenias (54,55).

Disorders of Hemostasis Associated with Bleeding

Hemostatic derangements complicated with bleeding are very common in pediatric patients with CHD. The holy grail of hemostatic testing would be one test that is rapidly available and adequately reports on all components of hemostasis. Unfortunately, this test does not exist, leaving clinicians with a series of coagulation tests that reflect various aspects of hemostasis.

Hemostatic testing: The PT and PTT serve as screening tests for procoagulant factor deficiencies. The PT and PTT do not provide a global picture of hemostasis. Proper specimen handling is imperative for coagulation assays. Heparin contamination of a specimen is the most common reason for a prolonged PTT in a hospitalized patient. Heparinase can be used to remove heparin from a specimen. Coagulation assays are also sensitive to the plasma-to-citrate ratio in the specimen tube. Underfilling of the specimen tube will falsely prolong the coagulation assays. Patients with significant polycythemia (hematocrit > 55%) can also have an altered plasma-to-citrate

ratio and will have falsely prolonged coagulation assays. A special specimen tube with a decreased amount of citrate should be used for patients with significant polycythemia. This is of particular concern when using the prothrombin time/international normalized ratio (PT/INR) to adjust warfarin dosing in cyanotic/polycythemic patients. Factor deficiencies that can cause an isolated prolonged PTT include either a deficiency in factor VIII, IX, XI, XII, prekallikrein or high molecular weight kininogen. An isolated prolonged PT is secondary to factor VII deficiency. Prolongation in both the PT and PTT can be seen in the setting of factor II, V, X, or fibrinogen deficiency.

For monitoring unfractionated heparin (uFH) therapy, the PTT is commonly used as a surrogate marker of heparin activity. For therapeutic heparin, the PTT is titrated to 1.5 to 3 times control. There are limitations to the PTT, especially it is affected by variables other than heparin including an elevated factor VIII, fibrinogen, or a Lupus anticoagulant. For example, when the FVIII level is >250%, the PTT is significantly shortened and will no longer reflect the heparin effect. (Factor VIII is an acute phase reactant and can be elevated in inflammatory states.) For a direct measure of heparin activity, the uFH anti-Xa level can be used with a recommended therapeutic range of 0.35 to 0.7 U/mL (note this is different from the LMWH anti-Xa-recommended therapeutic range of 0.5 to 1 U/mL).

The **activated clotting time (ACT)** is used to monitor higher heparin doses given to patients undergoing cardiac surgery with cardiopulmonary bypass (CPB), cardiac catheterization, or extracorporeal membrane oxygenation (ECMO). The ACT is a whole blood clotting time that is simple to perform with a rapid turnaround time. It is more sensitive to a wider range of heparin doses than the PTT. The limitations to this assay are that it is imprecise, proper specimen handling and timing are imperative, it is affected by the same variables that can prolong the PTT assay, and it is affected by the platelet count.

Fibrinogen is the final procoagulant protein in the coagulation pathway. It is converted by thrombin into fibrin. Fibrin is then cross-linked by factor XIII to make a stable clot. In the setting of a bleeding patient, it is imperative that the fibrinogen level is maximized to ensure adequate hemostasis. The **thrombin time** measures the conversion of fibrinogen to fibrin and is affected by quantitative or qualitative abnormalities of fibrinogen, the presence of thrombin inhibitors, and fibrinogen degradation products. Heparin contamination of the specimen can prolong the thrombin time.

For an assessment of primary hemostasis, a **platelet count** indicates the number of platelets that are available but does not provide any information regarding platelet function. At this time, there is a limited availability to rapidly assess platelet function. The **bleeding time** assesses platelet and capillary function but this technique is patient and operator dependent and has fallen out of favor (56). It is insensitive to mild platelet defects and does not consistently predict a bleeding tendency (57). The **platelet function analyzer (PFA-100)** is an in vitro screen for platelet function (57). The PFA-100 is prolonged in the setting of anemia or thrombocytopenia and is insensitive to mild platelet aggregation defects; it has also fallen out of favor as a screening test.

Thromboelastography (TEG) is a whole blood point-of-care assay that provides a real-time graph of clot formation and stability. Values measured include *R* (time necessary for initial clot formation), *K* (clot kinetics), α (rate of clot formation), maximum amplitude (maximum strength of the clot), and A-60 to maximum amplitude ratio (fibrinolysis). TEG has been utilized in pediatric CPB and in patients with LV assist devices (58–60).

Platelet mapping assay is a modification of the standard TEG and is used clinically to assess the effectiveness of antiplatelet medications. This assay utilizes whole blood that is heparinized to suppress thrombin generation, then known

platelet agonists are added to the sample to assess platelet activation. This assay is currently utilized most commonly in patients with a LV heart device to monitor antiplatelet therapy.

Acquired von Willebrand Disease

There is an increasing awareness of acquired von Willebrand disease (vWD) in patients with cardiovascular disorders. vWF is a procoagulant protein that has two important roles in hemostasis: it facilitates the binding of platelets to the site of vascular injury and it is the carrier protein for the coagulant protein FVIII. vWF is initially secreted as a large multimeric protein that is further proteolyzed by ADAMTS-13 into variable sizes of multimers. The distribution in the size of these multimers is imperative for hemostatic balance. For example, a bleeding tendency is seen with decreased vWF multimer size and a prothrombotic tendency is found when there is a persistence of ultra-large vWF multimers.

Most of the data on acquired vWD have focused on patients with aortic stenosis and with LV assist devices (61,62). There have been reports in neonates with patent ductus arteriosus, endocarditis, dysfunctional valve prosthesis, septal defects, and mitral valve prolapse (63,64). The pathophysiology of acquired vWD in cardiovascular disorders is likely multifactorial but thought to be secondary to lesions that result in increased shear stress. Increased shear stress results in the mechanical destruction of the larger vWF multimers and causes platelet activation that leads to the absorption of larger vWF multimers. Clinically, these patients will experience an increase in mucocutaneous bleeding and they could be at increased risk of hemorrhage with surgical procedures.

Laboratory findings in patients with cardiovascular disorders and acquired vWD reveal an abnormal multimer vWF distribution with a specific loss of the high molecular weight multimers. Commonly, the vWF antigen and activity are normal to increased. Routine coagulation testing PT/INR, PTT, and platelet count will be normal. Definitive treatment of acquired vWD would be to correct the underlying cardiac abnormality but this may not always be plausible (65). Other treatment modalities would include desmopressin (DDAVP) that facilitates the release of endogenous stores vWF, although the response rate is low (10%) in this setting (64). An alternative therapy would be the use of plasma-derived vWF replacement product (64,66). Treatment would only be necessary to treat active bleeding that does not resolve with local measures or prior to a significant hemostatic challenge to prevent excessive bleeding.

Platelet Disorders

Platelet disorders are either inherited or acquired. Congenital platelet disorders are very rare in the general population. Bernard-Soulier syndrome, a congenital platelet disorder, should be considered when caring for patients with 22q11.2 deletion syndrome. Bernard-Soulier syndrome is an autosomal recessive platelet disorder. The mutation is in the platelet GP 1b/IX complex that binds platelets to vWF. Children with 22q11.2 deletion syndrome can be heterozygotes for the Bernard-Soulier mutation given the proximity of the gene encoding the GP 1b/IX complex (67). Heterozygotes for this condition are clinically normal but may have mild thrombocytopenia and minor platelet function abnormalities (67). Patient with 22q11.2 deletion syndromes also have an increased prevalence of immune thrombocytopenia (ITP) (68,69).

In patients with cyanotic CHD, there is an inverse relationship between the platelet count and the degree of cyanosis. The lower the systemic arterial oxygen saturation, the higher will be the compensatory polycythemia. These physiologic changes are associated with a lower platelet count (70,71). Typically,

the thrombocytopenia is not severe and the platelet count will be $>50,000/\mu\text{L}$. The thrombocytopenia can improve with phlebotomy especially when the hematocrit is $>65\%$ (72). The etiology of thrombocytopenia in cyanotic CHD with polycythemia is unclear at this time.

Drug exposure is a common reason for acquired platelet dysfunction or thrombocytopenia. Antiplatelet medications are commonly used in patients with CHD to prevent thrombotic complications; these are discussed below. Numerous drugs have been implicated in causing thrombocytopenia. The more commonly used drugs include antibiotics (penicillins, or sulfa-containing antibiotics), antiepileptics (phenytoin, valproate, carbamazepine), H₂ agonists (cimetidine or ranitidine), thiazide diuretics, and furosemide. In general, thrombocytopenia will resolve with removal of the offending drug. A special circumstance of drug-induced thrombocytopenia is heparin-induced thrombocytopenia (HIT).

HEPARIN-INDUCED THROMBOCYTOPENIA

HIT is the result of antibodies that are formed against the heparin-PF4 complex that exists on platelets (73). It is proposed that the binding of antibodies to this platelet complex results in increased platelet reactivity and thus a prothrombotic state (73). This disorder is characterized by thrombocytopenia and resultant arterial and/or venous thrombosis that can be catastrophic. In adults, the prevalence of HIT is estimated to be 1% to 5% of patients exposed to heparin and untreated HIT has a mortality of 20% to 30% (74). The incidence of HIT in the pediatric population is not clearly defined but appears to be less than adults with a reported range of 0% to 2.3% (75–78). Higher risk pediatric groups include patients undergoing CPB (79).

The diagnosis of HIT is based on clinical criteria. Multiple scoring systems have been developed and validated in adults but not in pediatric patients (80–82). Classically, HIT is characterized by symptoms appearing 5 to 10 days post-heparin exposure with a 50% fall in the platelet count (rarely is the platelet count $<50,000/\mu\text{L}$) and there can be venous or arterial thrombosis. Laboratory testing can be supportive in making the diagnosis and includes ELISA for the heparin-P4 antibodies and the serotonin-releasing assay. The ELISA are readily available with a fast turnaround time. This test is highly sensitive but has a significant false positive rate. The ELISA is most helpful in ruling out the diagnosis with a negative assay. The serotonin-releasing assay is highly specific and sensitive; it measures platelet reactivity in the presence of the patient's plasma. Unfortunately, it is only performed in a few highly specialized laboratories so is not readily available for most clinicians.

The treatment of HIT includes the removal of all heparin from the patient including avoidance of LMWH. Anticoagulation should be initiated with a non-heparin anticoagulant such as a direct thrombin inhibitor (i.e., bivalirudin or argatroban). In this setting, warfarin should never be initiated by itself due to an increased risk of skin necrosis and further thrombotic events. Warfarin can be initiated once the platelet count has normalized and overlapped with the nonheparin anticoagulant until the INR is therapeutic.

Additional causes of acquired thrombocytopenia in pediatric patients with CHD include sequestration and consumptive causes. The spleen normally contains 30% of the platelet mass, and in the setting of an enlarged spleen, it can trap a larger portion of platelets with resultant thrombocytopenia. In patients with CHD, specific consumptive causes of thrombocytopenia include CPB and artificial heart valves or grafts. Other causes of consumption not necessarily specific to patients with CHD include the use of ECMO, the presence of disseminated intravascular coagulation, thrombotic thrombocytopenic purpura,

hemolytic uremic syndrome, hemophagocytic lymphocytic histiocytosis, HIV, or immune destruction of platelets.

IMMUNE THROMBOCYTOPENIA

ITP is an immune-mediated destruction of platelets generated by the presence of IgG autoantibodies. These antibodies coat the surface of the platelets and these platelets are cleared through the Fc γ receptors in the spleen. In childhood, ITP is considered a benign self-limited disorder; 80% of patients spontaneously resolve within 6 months with only a small percentage (<20%) developing chronic ITP. Treatment can include observation combined with thrombocytopenic precautions or the use of immune-modulating therapies like immune globulin or steroids. In the neonate, immune destruction of platelets can be secondary to a mismatch between the fetal and maternal platelets, termed neonatal alloimmune thrombocytopenia. The mother develops antibodies against antigens on the fetal platelet surface that were inherited from the father. These antibodies cross in the placenta, coat the fetal platelets, and result in significant thrombocytopenia. Thrombocytopenia can also be the result of decreased production that can be found in aplastic anemia, myelodysplastic syndrome, infiltrative marrow processes (i.e., leukemia), or nutritional deficiency states.

THROMBOCYTOSIS

Thrombocytosis is defined as an increase in the platelet count that is two standard deviations above the mean value for age. Thrombocytosis can be primary or secondary. Primary causes include myeloproliferative disorders that are either inherited (essential thrombocythemia) or acquired (polycythemia vera, leukemia, or myelodysplastic syndrome). Secondary causes are the result of underlying inflammation (infection, rheumatologic disorders, or inflammatory bowel disease), hematologic disorders (hemolytic anemia or iron deficiency), drugs (vinca alkaloids or corticosteroids), or decreased splenic pooling in the setting of asplenia.

CPB, ECMO, and Ventricular Assist Devices

Postoperative Bleeding after CPB

Postoperative bleeding is a common complication in pediatric patients undergoing CPB and is associated with increased morbidity and mortality (83,84). CPB is a nonphysiologic state and the passage of blood through the artificial circuit results in the activation of the coagulation, fibrinolytic, and inflammatory systems. The coagulation system is activated through the contact pathway and ultimately results in the formation of fibrin. With fibrin deposition within the CPB circuit, there is platelet adherence and activation. Prematurely activated platelets are no longer available for hemostasis.

Post-CPB bleeding is more common in pediatric patients than in adults. Clinical factors associated with postoperative bleeding include younger age (<1 year), lower weight (<8 kg), cyanosis, prolonged circuit, and deep hypothermia times (85–87). One major contributing factor is the degree of hemodilution that occurs in pediatric patients with the institution of cardiac bypass. This is secondary to the large discrepancy between a pediatric patient's blood volume and the circuit volume. An adult patient experiences approximately 25% hemodilution with the institution of bypass, while a pediatric patient can experience up to 60% of hemodilution (88). This dilution is further exacerbated by developmental hemostasis in neonates who, at baseline, already have lower procoagulant and anticoagulant proteins (4).

To prevent postoperative CPB bleeding, multiple approaches have been utilized including adequate anticoagulation during CPB, modified ultrafiltration, adequate reversal of

anticoagulation post-CPB, transfusion of blood components, and antifibrinolytics (88). High-dose heparin is used during CPB to prevent thrombosis of the circuit. Heparin exerts its anticoagulant effect through the binding of antithrombin. Neonates developmentally have lower antithrombin levels that can contribute to a variable heparin effect. There are also significant issues with monitoring heparin therapy during CPB in pediatric patients. It has been shown in children that the ACT values do not correlate with heparin levels. Specifically, the ACT overestimates the heparin effect because it is prolonged by other variables including hemodilution and hypothermia (88–90). Adequate reversal of heparin with protamine is dependent on knowing the correct heparin concentration. Too little protamine means heparin is still circulating or excessive unbound protamine has anticoagulant properties (91,92). Hyperfibrinolysis is also an important mechanism that leads to post-CPB bleeding (93,94). All three antifibrinolytic therapies (aprotinin, tranexamic acid, and aminocaproic acid) have been shown to decrease post-CPB hemorrhage (95). Aprotinin was removed from the US market in 2008 because of its association with renal failure and death in adult recipients (95,96). Despite the use of these therapies, hemorrhage following CPB remains a frequent occurrence.

MANAGEMENT OF POSTOPERATIVE BLEEDING

Although some bleeding from indwelling mediastinal drains is expected after cardiac surgery, the rate of bleeding should decrease as each postoperative hour goes by. Excessive bleeding is a clinical concern that warrants immediate attention and constant vigilance. In the immediate postoperative period, bleeding of <5 mL/kg/h is often associated with minor abnormalities in coagulation status. Red cell transfusion may be necessary to correct a postoperative anemia but blood component administration is rarely necessary. Bleeding 5 to 10 mL/kg/h should prompt notification of the cardiothoracic surgeon and continued evaluation of the patient at the bedside. Any abnormalities in coagulation parameters should be corrected. Blood loss must be balanced by RBC transfusion. The patient must be closely monitored for persistence or an increase in the rate of bleeding that may signal the presence of a surgical bleeding site or may be the result of loss of coagulation factors secondary to the ongoing hemorrhage. Bleeding of >10 mL/kg/h that persists or increases will likely result in hemodynamic compromise if not abated. The cardiothoracic surgeon should decide whether reexploration is needed to exclude a bleeding site or to remove thrombus that may be perpetuating further bleeding. The cardiac intensivist must exclude concomitant hemothorax and/or hemothorax (often heralded by tachycardia, hypotension, desaturation, and/or tamponade physiology) while keeping up with the blood loss (RBC transfusion) and coagulopathy (blood component replacement). Even when the decision is made to go back to the operating room, the bedside medical team must continue to be vigilant with RBC, volume, and blood component replacement as indicated by hemodynamic parameters and laboratory data.

Recombinant factor VIIa (rFVIIa, eptacog alfa (activated), NovoSeven, Novo Nordisk Pharmaceuticals Inc., Princeton, NJ) is currently utilized as an off-label hemostatic agent in the management of postoperative CPB bleeding. It is an analogue of the naturally occurring procoagulant factor VII and induces hemostasis by binding to exposed tissue factor at the site of endothelial injury and stimulating thrombin formation (97,98). Current studies indicate that children and adults with cardiovascular disease account for a large proportion of off-label rFVIIa use (99,100).

There are concerns regarding the thrombotic potential of rFVIIa and this concern is further heightened in pediatric patients with CHD because of a known increased incidence of thrombosis (101). Current evidence to support

off-label use of rFVIIa in CPB in children is limited. Only one pediatric randomized clinical trial of rFVIIa in CPB has been conducted and it was found that there was no benefit to the prophylactic use of rFVIIa among 82 infants undergoing surgery for correction of CHD (102). The primary end point, time to chest closure, was actually prolonged in the treatment group. No difference was noted in the secondary end points of surgical blood loss or use of blood products (102). A recent systematic review regarding the off-label use of rFVIIa in pediatric cardiac surgery reviewed 29 studies that included a total of 169 patients (103). The authors concluded that there is no supporting evidence to use rFVIIa prior to cardiac surgery to prevent bleeding. Randomized clinical trials should be performed that utilize appropriate clinical outcomes to address the use of rFVIIa to treat bleeding after cardiac surgery. Therapeutic options for postoperative bleeding are listed in Table 75.2.

ECMO and Ventricular Assist Devices

Patients on ECMO or who have ventricular assist devices are at increased risk for both bleeding and thrombotic complications. Similar to CPB, both processes have the passage of blood through an artificial circuit resulting in activation of coagulation. Anticoagulation remains the mainstay to prevent thrombotic outcomes. In ECMO, uFH is commonly used for anticoagulation. In patients with a ventricular assist device, one type of anticoagulation (uFH, LMWH, or warfarin) is combined with antiplatelet therapy.

Thrombosis

Thrombosis in Children and Adolescents with Congenital and Acquired Heart Disease

Thrombosis has long been recognized as a clinical problem to the clinician caring for adolescents and children with congenital and acquired heart disease. Much work has focused on the diagnosis, treatment, and prevention of thromboses in Kawasaki disease (104–107) and to a lesser extent on the thrombotic complications associated with cardiac catheterization (108–111) or cardiomyopathies (112,113). The prevention and management of thromboses related to prosthetic valves (114), arrhythmias (115,116), and PH (117,118) in children has largely been extrapolated from the adult literature. For the past decade, the single ventricle population has been identified as a particularly high-risk population for thrombosis and their potentially devastating sequelae (119–128).

Overall, there is a paucity of information on the true scope of thrombotic complications in children and adolescents with heart disease. Two retrospective studies reviewed thrombotic incidence and risk factors in cardiovascular surgical populations. Early limited work by Giglia et al. in 2001 (129) reported a 3.6% incidence of clinically evident thrombi from a survey of pediatric cardiovascular patients over a 9-year period (1,940 total operations). Mean time from operation was 2.6 months; mean time from operation was 21 days. Deep venous thromboses associated with indwelling central lines were the most common. Of those with thrombi, 20.8% were felt to have died as a direct result of the thrombus. In 43.4%, the diagnosis was felt to have been delayed, and in 17.0%, it was not made until autopsy. A recent retrospective review by Manlhiot et al. (130) of 1,542 pediatric cardiothoracic operations at a single center reported an 11% incidence of clinically evident as well as silent thrombi identified by testing ordered by the attending physician. Factors associated with increased odds of thrombi were age <31 days, baseline oxygen saturation <85%, previous thrombosis, heart transplantation, use of deep hypothermic circulatory arrest, longer cumulative time

with central lines, and postoperative use of ECMO. Serious complications occurred in 28% of patients with thrombi and were associated with thrombus location (intrathoracic, the highest risk), symptoms, and partial/full occlusion. Thrombosis was associated with a longer ICU and hospital stay, and a higher odds ratio of cardiac arrest, catheter reintervention, reoperation, and mortality. Much work is still needed in the area of diagnosis and treatment and most importantly in defining risk factors so that these potential life-threatening complications can be prevented.

The Propensity for Thrombosis in Adolescents and Children with Congenital and Acquired Heart Disease

Congenital and acquired heart disease put adolescents and children at risk for thrombosis mainly because the triad of risk factors for thrombosis initially described by Virchow (131) in 1856 is often at play. These factors are (a) stasis of blood flow, (b) hypercoagulability, and (c) endothelial injury. However, the risk for thrombosis in pediatric heart disease warrants an expansion of Virchow's triad. Turbulent blood flow across abnormal cardiac structures, that is, stenotic valves, can lead directly to platelet activation (132), making "altered blood flow" more applicable to pediatric heart disease than "static blood flow" alone. In addition, advances in cardiothoracic surgery have introduced CPB, which is well associated with thrombotic risks, as well as the use of other nonendothelial surfaces, such as prosthetic valves, graft materials, and indwelling catheters, that are in and of themselves thrombogenic. Also, recent work has found children with CHD to have a higher incidence of coagulation abnormalities than children without CHD; this includes children with acyanotic heart disease as well as the more widely studied single ventricle population (121,122,125,126,133–138). Therefore, risk factors for thrombus in adolescents and children with heart disease should be expanded to include:

1. Hypercoagulability:

Coagulation abnormalities have been identified to include altered coagulation protein levels, decrease endogenous inhibitors of coagulation, and decreased fibrinolytic proteins among others. Such coagulopathies were first identified in children and adolescents with a Fontan circulation but more recently have been found in children through all stages of single-ventricle palliation and also in children with acyanotic and acquired heart disease (121,122,125,126,133–138). Table 75.3 lists the thrombophilia evaluation. The thrombophilia evaluation can assist the clinician in determining a patient's recurrent risk for thrombosis and the appropriate duration of therapy.

2. Altered blood flow

- a. **Stasis:** may occur in dilated heart chambers as well as in dilated native or prosthetic outflow tracts. These areas of stasis serve as a nidus for thrombus formation.
- b. **Turbulent flow:** is a flow across stenotic native or prosthetic heart valves, stents, and/or obstructed outflow tracts with increased sheer stress that can result in platelet activation independent of endothelial damage (139).
- c. **Endothelial disruption:** occurs from turbulent flow on endothelial surfaces as well as vessel wall endothelial damage from insertion and persistence of central lines and catheters. Endothelial injury, as discussed previously, exposes tissue factor and subendothelial collagen-stimulating platelet aggregation and coagulation at the site of injury. Note, platelets can also be activated by other mechanisms in addition to endothelial injury such as from cytokines release during inflammation (139–141).

TABLE 75.2 Therapeutic Options for Postoperative Bleeding

Product	Mechanism	Dose	Indication	Side Effects
Fresh frozen plasma	Contains all clotting, anticoagulant, and fibrinolytic proteins	10–15 mL/kg	Bleeding associated with a coagulopathy (multiple factor deficiencies)	Allergic reaction Fever Volume overload TRALI (rare)
Cryoprecipitate	Fibrinogen (Also contains factor VIII, vWF, and factor XIII)	1–2 U (bags)/10 kg	Bleeding associated with a fibrinogen deficiency	Allergic reaction Fever TRALI (rare)
Platelets	Platelets	<35 kg 10 mL/kg >35 kg 1 SDP (with a maximum volume of 15 mL/kg)	Bleeding from thrombocytopenia	Allergic reaction Fever Volume overload TRALI (rare)
Aminocaproic acid	Synthetic lysine analogue that inhibits plasmin. Prevents fibrinolysis	100 mg/kg Q6 hours (maximum daily dose 30 g)	Bleeding associated with excessive fibrinolysis	Nausea/emesis Abdominal pain Dizziness Thrombosis
DDAVP **Off-label use**	Synthetic analogue of DDAVP, increases factor VIII and vWF levels and activates platelets	0.3 µg/kg q12 hours <i>Tachyphylaxis (no longer has a hemostatic effect) after 3–4 doses</i>	Severe bleeding resistant to maximized component therapy. <i>Suggest a hematology consult</i>	Hypotension tachycardia Free water retention with an associated risk of hyponatremia Thrombosis
Prothrombin complex concentrates (PCC) **Off-label use**	Contains factors II, VII, IX, and X (some PCCs also contain protein C and S)	No RCTs in this setting to guide dosing 20–25 IU/kg	Severe bleeding resistant to maximized component therapy. <i>Suggest a hematology consult</i>	Plasma-derived product Allergic reaction Thrombosis
rFVIIa **Off-label use**	Analogue of the naturally occurring procoagulant factor VII. Induces hemostasis by binding to exposed tissue factor at the site of endothelial injury and stimulating thrombin formation	No RCTs in this clinical setting to guide dosing. Wide dose ranges have been reported (17–200 µg/kg) Lower doses are advisable 40–60 µg/kg	Severe bleeding resistant to component therapy. *Suggest a hematology consult	Allergic reaction Thrombosis

SDP, single donor, apheresis platelet product; RCT, randomized clinical trials; TRALI, Transfusion-related acute lung injury.

d. **Prosthetic materials:** may result in turbulent flow that activates platelets. Activated platelets will adhere to these “abnormal” artificial vascular surfaces, that is, ECMO surface, prosthetic valves, and intravascular stents. Again activated platelets and an abnormal vascular service may result in pathologic thrombus (125–127,142).

- **Mechanical support:** including CPB, ECMO, and ventricular assist devices have thrombotic risk potential despite systemic anticoagulation. The procoagulant state may extend beyond the time of decannulation (143). Interestingly, all of the above-mentioned risk factors including coagulation abnormalities, altered blood flow, endothelial damage, and abnormal vascular surfaces are operative.

3. Inflammation and bloodstream infection:

Tissue factor has been documented to become accessible via activated monocytes or endothelial cells when stimulated by sepsis or through cytokine production during inflammation (140,142). In recent clinical studies, sepsis was associated with increased thrombus formation especially in the presence of an indwelling central venous catheter (144–146).

Consequence of Significant Thrombi in Adolescents and Children with Cyanotic Heart Disease

Adolescents and children with cyanotic heart disease are at particular risk of devastating complications from both venous as well as arterial thrombi. Whereas stroke, limb compromise, and pulmonary emboli are the major risks in patients with separated circulations, patients with CHD have additional life-threatening risks, namely the following:

1. Occlusion of systemic-to-pulmonary shunts or Fontan circuits are both lethal without immediate intervention.
2. Postcatheterization arterial or venous thrombotic occlusions may make performance of further essential diagnostic and/or therapeutic cardiac catheterizations difficult to impossible.
3. Occlusion of large veins of the upper body may make it impossible for a single-ventricle patient to go on to a bidirectional cavopulmonary anastomosis or to a Fontan palliation, rendering transplant the only long-term option.

Common Thrombotic Complications in Congenital Heart Disease

Table 75.4 lists the commonly used antiplatelet, anticoagulant, and thrombolytic therapies and includes mechanisms of actions, pharmacokinetics, dosing, monitoring, and reversal.

EARLY POSTOPERATIVE THROMBOSES

Patients in the early postoperative period may be at particular risk for thrombotic events secondary to effects of CPB (see discussion), use of indwelling central lines, immobilization, pleural effusions, low cardiac output, and/or intravascular depletion. There is evidence that sepsis may further increase the thrombotic risk (144,145).

The presentation of perioperative thrombi may be insidious, for example, low-grade fever and/or thrombocytopenia from platelet consumption in the thrombus. The diagnosis may be equally elusive since thrombi may be missed by routine imaging (echocardiography or ultrasound) unless there is a high degree of suspicion and vigilance in imaging. Areas notorious for difficult-to-image thrombi are Fontan baffles/conduits and right ventricular outflow tract patches/conduits, both of which are often seated anteriorly, limiting noninvasive imaging.

Although, to date, there are no established guidelines to minimize the risk of early postoperative thrombi, it appears prudent to

- recognize the potential triggers of thrombosis (younger age, baseline oxygen saturation <85%, previous thrombosis, heart transplantation, use of deep hypothermic circulatory arrest, longer cumulative time with central lines, postoperative use of ECMO, immobilization, pleural effusions, low cardiac output, intravascular depletion, polycythemia, or sepsis)
- minimize these risk factors whenever possible (i.e., assess the need for central lines daily and removal central lines as early as possible, avoid intravascular depletion)
- recognize the signs of perioperative thromboses (limb edema, ascites, pleural effusions, superior vena cava [SVC] syndrome, unexplained desaturation, i.e., from pulmonary emboli)
- always be suspicious of thrombi in high-risk patients and proceed to imaging studies as clinically indicated.

The efficacy of prophylactic heparin to prevent central venous line (CVL)-associated thrombi in children has not been established. The PROTEKT trial (147) did not find a benefit to using LMWH in preventing CVL-associated thrombi in a general pediatric population. More recently, low-dose, continuous infusion of uFH was not protective in infants after cardiac surgery (148). It is unclear, however, whether subgroups exist where such prophylaxis may be beneficial (i.e., CVL in the SVC or inferior vena cava [IVC] in children who anticipate a cavopulmonary anastomosis procedure in the future, children with CVL and concomitant bacteremia, or children with prior thrombi or other hypercoagulable risk factors).

SINGLE VENTRICLE POPULATION

Children at each stage of single-ventricle palliation are potentially at increased risk for thrombotic complications.

Aortopulmonary Shunts Thrombosis: Prevention and Treatment

An aortopulmonary shunt is often required in infants with cyanotic CHD either as palliation to a two-ventricle repair (i.e., in Tetralogy of Fallot) or as part of a staged single-ventricle palliation as in the Norwood procedure for hypoplastic left heart syndrome. Risk factors for shunt thrombosis include dehydration, pleural effusions, shunt distortion, and

TABLE 75.4 Common Antiplatelet, Anticoagulant, and Thrombolytic Therapies Utilized in Pediatric Patients with CHD

Drug Name	Mechanism of Action	Pharmacokinetics	Dosing	Therapeutic Monitoring	Reversal
ASA	Irreversibly acetylates cyclo-oxygenase impairing platelet prostaglandin metabolism and synthesis of thromboxane	Half-life 15–20 min Rapidly absorbed in proximal GI tract. Platelet inhibition achieved in 60 min	Low dose: 1–5 mg/kg/d	None	Platelet transfusion
Dipyridamole	Inhibits phosphodiesterase enzymes that break down cAMP and block the platelet uptake of adenosine	Half-life 10 h Elimination primarily through biliary excretion	2–5 mg/kg divided every 6–8 h	None	Platelet transfusion
Clopidogrel	Irreversibly inhibits ADP-induced platelet aggregation	Half-life 8 h Requires hepatic activation Platelet inhibition within 2 h of oral dose	0.2 mg/kg/d	None	Platelet transfusion
uFH	Binds to antithrombin and potentiates anticoagulant activity 1,000-fold. The heparin/AT complex inactivates factors IIa (thrombin), Xa, XIa, and XIIa	Half-life 0.5–2.5 h	Age <12 mo Bolus 75 U/kg 28 U/kg/h Age > 1 y–12 y Bolus 75 U/kg 20 U/kg/h Age >12 y Bolus 80 U/kg 18 U/kg/h	Titrate dose by PTT or anti-Xa level PTT: 1.5–3 times control uFH anti-Xa level: 0.35–0.7 U/mL	Protamine sulfate
LMWH (i.e., enoxaparin)	Binds to AT and potentiates anticoagulant activity. Same inhibition as uFH but has a reduced inhibitory activity against factor IIa (thrombin) relative to factor Xa	Half-life 3–6 h Renal clearance	Enoxaparin dosing Age <2 mo 1.5 mg/kg q12 h Age >2 mo 1 mg/kg q12 h	Titrate dose by LMWH anti-Xa peak level: 0.5–1 U/mL (drawn 4 h after the second or third dose)	Protamine sulfate (only a partial reversal, 70%)
Bivalirudin	Inhibition of factor IIa (thrombin) by reversibly binding the active catalytic and substrate binding site	Half-life 25 min Renal clearance is 20%	Bolus: 0.125 mg/kg Maintenance: 0.125 mg/kg/h	Titrate dose by PTT PTT: 1.5–3 times control	None
Argatroban	Inhibition of factor IIa (thrombin) by reversibly binding the active catalytic site	Half-life 45 min Metabolized in liver	0.75–1 µg/kg/min	Titrate dose by PTT PTT: 1.5–3 times control	None
Warfarin	Interferes with the cyclic conversion of vitamin K through the inhibition of vitamin K epoxide reductase. There is a resultant decrease in the posttranslational γ-carboxylation of vitamin K–dependent clotting factors II, VII, IX, and X as well as anticoagulant protein C and S	Half-life 20–60 h	No loading dose: Age 2–10 y 0.09 mg/kg/d Age >12 y 0.08 mg/kg/d	Titrate dose by INR INR: 2.0–3.0	Vitamin K Fresh frozen plasma
Tissue plasminogen activator (tPA)	Converts plasminogen to plasmin. Plasmin cleaves fibrin leading to clot dissolution	Half-life 5 min	Systemic thrombolysis: Low dose: 0.03–0.06 mg/kg/h (max 2 mg/h) High dose: 0.1–0.6 mg/kg/h (max 50 mg/h) <i>Reassess at 6 h</i>	Monitor closely for bleeding. Follow CBC, PT, PTT, fibrinogen, D-dimer every 4–8 h while on the infusion An elevated D-dimer and drop in fibrinogen is indicative of a lytic state	None

AT, antithrombin; PTT, partial thromboplastin time; PT, prothrombin time; INR, international normalized ratio; CBC, complete blood cell count.

bloodstream infection. Complete or near-complete thrombosis of an aortopulmonary shunt is a medical emergency requiring prompt recognition, diagnosis, and treatment.

Most centers recommend the following:

- Systemic anticoagulation via immediate administration of an intravenous bolus of uFH (50 to 100 U/kg) followed by a continuous heparin infusion.
- Maneuvers to increase systemic blood pressure thereby increasing shunt flow (phenylephrine, epinephrine)
- Maximize oxygen delivery and minimize oxygen consumption (intubation, mechanical ventilation, muscle paralysis)

Definitive diagnosis is usually made angiographically. Occlusion or near-occlusion must be treated expeditiously with intravascular stenting, manual shunt manipulation, or shunt revisions. ECMO may be necessary for stabilization or resuscitation. Systemic thrombolytic therapy is usually not used in aortopulmonary shunt occlusion since it may complicate subsequent emergent catheterization and/or surgery.

Partial shunt thrombosis presents with unexplained O₂ saturations lower than baseline without another etiology. An angiogram is usually recommended for confirmation since concomitant balloon dilation may be helpful for nonocclusive thrombus and stent placement for distortion or kinking at the insertion site. (149,150)

Low-dose aspirin (ASA) has become the standard of care for chronic prophylaxis in infants with aortopulmonary shunts. In 2005, Wells et al. (151) examined 155 polytetrafluoroethylene shunts at elective takedown and reported 21% with >50% luminal narrowing. Li et al. (152) in 2007 reported the results of a multicenter study that evaluated 1-year postoperative rates of death, shunt thrombosis, and early stage II operation in 1,004 infants. Around 80% received ASA. Event rates were 38% for the composite end point, 26% for death, and 12% for shunt thrombosis. Excluding early postoperative mortality, patients receiving ASA had a lower risk of shunt thrombosis and death compared with those not receiving ASA. Adding clopidogrel to chronic low-dose ASA did not reduce overall mortality or shunt-related morbidity in an early report (153). Despite chronic ASA therapy, shunt-related morbidity and mortality remains high. Investigation into alternative means of thrombosis prevention in these high-risk populations is warranted.

Bidirectional Glenn Anastomosis

Few data are currently available regarding the overall incidence and risk factors for thrombotic complications after a bidirectional cavopulmonary anastomosis beyond the early postoperative period. Certain high-risk groups have been identified and include patients with bilateral SVC (low flow in the interconnecting pulmonary artery segment) (154), a blind-ending pulmonary artery stump (155), and interrupted inferior vena cava with azygous continuation to the SVC (resultant Kawashima palliation). (120) Although Odegard et al. (134,156) have documented coagulation abnormalities in children post-stage II and pre-Fontan, there are no clear recommendations for chronic anticoagulation in children after the bidirectional Glenn anastomosis or hemi-Fontan operation. Antiplatelet therapy may be reasonable although prospective data are lacking. A few centers are advocating prophylactic anticoagulation. Clearly more work is needed in this area. At any stage in the single ventricle pathway, certain factors, in addition to those mentioned above, may put a patient at increased risk for thrombosis including flow stasis, ventricular dysfunction, previous thrombosis, protein-losing enteropathy, prolonged pleural effusions, arrhythmias, prolonged immobilization, and/or an abnormal thrombophilia profile. Initiation of prophylactic anticoagulation therapy or increasing the magnitude

of antithrombotic therapy (from antiplatelet to anticoagulant) may warrant consideration in such circumstances.

Fontan

There has been much interest over the past 20 to 30 years in thrombosis after the Fontan operation (123,124,127,157–164). The incidence of thrombotic complications after the Fontan operation has been reported to be 3% to 33% overall (1.4 to 3.6 for stroke) depending on the population studied, the time from the Fontan procedure, the method of thrombosis detection, the location of the thrombus investigated (i.e., pulmonary embolus vs. cerebral vascular event), or whether the study investigated clinically evident or silent thrombi. Although these reviews are an important source of observational data, their heterogeneous designs limit the ability to draw conclusions from which practice guidelines can be generated. The following observations, however, can be made:

- There appear to be two peaks in the incidence of thrombotic complications post-Fontan: early (3 to 6 months postoperatively) and late (5 to 10 years after the Fontan) (159,161,165).
- Thrombi have been identified in systemic venous atrium, pulmonary venous atrium, hypoplastic ventricle, ligated pulmonary artery stump, extracardiac, lateral tunnel and aortopulmonary pathways, silent pulmonary emboli, and thrombi in conjunction with HIT.
- Identified risk factors for thrombosis include flow stasis, ventricular dysfunction, arrhythmias, bilateral bidirectional cavopulmonary anastomoses, hypoplastic cardiac chambers with flow stasis, presence of a blind ended pulmonary artery stump, Kawashima connection, history of previous thrombosis, protein-losing enteropathy, prolonged pleural effusions, and prolonged immobilization.

There are limited retrospective reviews on the use of prophylactic anticoagulation after the Fontan operation. Seipelt et al. (161) in 2002 concluded that warfarin was indicated in patients post-Fontan. Jacobs et al. (123) also in 2002 concluded that ASA was sufficient prophylaxis although his patient population was limited to young children in the early post-Fontan years. Kaulitz et al. (127) in 2008 presented a retrospective review of a strategy that adjusted antithrombotic therapy depending on the development of prothrombotic risk factors over time.

The only published clinical trial to date was reported by Monagle et al. (128) in 2011. In this multicenter, randomized trial of primary prophylactic anticoagulation after the Fontan operation, patients were randomized to receive for 2 years either warfarin (started within 24 hours of uFH lead-in of 10 to 20 U/kg/h, target INR 2.0 to 3.0) or ASA (5 mg/kg/day) started as soon as they were able to tolerate oral intake. Transthoracic and transesophageal echocardiograms were performed at 3 and 24 months post-Fontan. There was no difference in thrombus detection between the two groups; thrombi were identified in 24% of those receiving warfarin and 21% of those receiving ASA. All thrombi were venous, 72% were detected on routine echocardiogram, and 28% were associated with clinical signs/symptoms. Seven of the 25 patients had thrombi in multiple locations; 20 within the Fontan connection; 4 within the pulmonary arteries; 7 within other venous sites. For those receiving warfarin, the mean INR at the time of thrombus detection was 2.2. At routine surveillance, 41% were below target INR and 14% above. Thrombi were detected by transthoracic echo in 52% and by transesophageal echo in 84%. Thrombi were generally treated with uFH (one patient required a thrombolytic agent). Thrombosis recurred in 28% despite an increase in the level of anticoagulation after the initial thrombotic event. Two patients required operation,

one a complicated Fontan revision followed by multiorgan failure and death (ASA group) and the other a Fontan take-down after initial thrombosis (warfarin group). Although there was no difference in the incidence of thrombi in the warfarin versus ASA group, the incidence of thrombi in both groups was unacceptably high. In addition, the study further points out the difficulty with warfarin administration in young children with 41% below target INR at routine surveillance further emphasizing the need for alternative therapies to both warfarin and ASA. It is important to realize, however, that this study only evaluated patients during the first 2 years after the Fontan. The second peak in thrombosis risk (5 to 10 years post-Fontan) warrants rigorous investigation as well.

Conclusions that can be drawn from the currently available data regarding monitoring and prophylaxis of the Fontan patient:

- Since the risk for thrombotic complications may change over time, repeated clinical screening for changes in anatomic and hemodynamic risk factors appears indicated.
- Close monitoring for thrombosis with periodic transthoracic echocardiography with focused attention to the identification of thrombi should be a part of routine of post-Fontan care. Additional imaging modalities (transesophageal echo, CT, computed tomography angiography (CTA), MRI, nuclear medicine lung perfusion scan, and venography/angiography) may be useful in patients with thrombosis suspected clinically or in whom transthoracic images are suboptimal.
- There is growing evidence that certain patients are “repeated clotters” and their propensity to thrombosis may warrant a higher level of surveillance and possibly a higher level of prophylaxis (128).
- Antiplatelet therapy for prophylactic long-term anticoagulation appears reasonable after the Fontan operation.
- An increase in the magnitude of antithrombotic therapy (change in medication from antiplatelet to anticoagulant or higher target levels) may be warranted if anatomic and/or hemodynamic risk factors become present.
- Further identification of risk factors, patients at particular individual risk (“clotters”), alternative agents, as well as alternative management strategies are essential.

PROSTHETIC VALVES

Prosthetic valves are used in both the atrioventricular and semilunar valve positions in children and adolescents with both congenital and acquired heart disease. This differs from adults with non-CHD where right-sided valve replacement is very uncommon. Two classes of valves are available: mechanical and bioprosthetic. Bioprosthetic valves, also referred to as “tissue valves,” are allografts or xenografts (bovine or porcine). Mechanical valves have a higher durability but require systemic anticoagulation, with a higher degree of anticoagulation theoretically required on the right side of the heart secondary to the lower pressures and the lower flow velocities. Long-term systemic anticoagulation is usually not required with bioprosthetic valves although they are less durable than mechanical valves with rapid deterioration in children especially in the aortic and mitral positions. Bioprosthetic valves, however, are more durable on the right side compared with the left side of the heart. Based on the above observations, mechanical valves are usually used in the mitral position and bioprosthetic valves on the pulmonary side. Since systemic anticoagulation with a vitamin K antagonist (VKA), most commonly warfarin, is difficult especially in young children, a few centers are attempting bioprosthetic valves in the mitral position in the hope that medium-term anticoagulation will not be necessary and the valve may last long enough until upsizing is needed at an older age when a mechanical valve may be more feasible.

Despite prescribed anticoagulation with warfarin, patients with mechanical valves are still at increased risk for both bleeding and clotting. A single, prospective, multicenter study of children <5 years of age at mitral valve replacement with a mechanical prosthesis (average follow-up 6.2 years, no time to event analysis) reported thrombotic events in 3% and stroke in 2% (target and achieved INRs were not reported) (166). The risk for thrombotic complications is less with mechanical aortic valves. Several retrospective studies in pediatric patients report the risk of thrombotic complications as 0% to 1.3% per patient per year and the risk of bleeding as 0% to 2.3% per patient per year (167–178). Tricuspid valve replacement is rare with Ebstein anomaly the most common indication and bioprosthetic valves most commonly employed. Mechanical valves are rarely used in the tricuspid position, and when they are used, an increased level of anticoagulation has been recommended because of the decreased flow velocity. Although reports are limited and mainly in adults, the risk of thrombosis appears to be high despite anticoagulation. One study reported a 2.9% per patient per year risk of valve thrombosis despite target INR of 2.0 to 3.0 (179). Another study in adult patients only reported a 15.4% incidence of tricuspid valve thrombosis despite a target INR of 2.5 to 3.5 with a mean follow-up of 7.9 years (180).

Bioprosthetic valves in the pulmonary position have a low risk for thrombosis and essentially no risk for systemic embolization. There are no data to support systemic anticoagulation for a bioprosthetic valve in the pulmonary position. As discussed above, tricuspid valve replacement is rare, with Ebstein anomaly being the most common indication. Although bioprosthetic valves are more commonly used in this situation, reports from a large experience at the Mayo Clinic recommend anticoagulation with a VKA for 3 to 6 months postoperatively (target INR 2.0 to 3.0) and lifelong with ASA (181–183).

Since there is a paucity of data on the efficacy and safety of anticoagulation strategies for prosthetic valves in children and adolescents, most centers and experts in the field follow the guidelines established for adults by the American College of Cardiology and the American Heart Association revised in 2008 (114,184) and those of the American College of Chest Physicians published that same year (185). Prophylactic anticoagulation guidelines for adults with prosthetic aortic and mitral valves are outlined in Table 75.5. Although not common practice in pediatrics, these guidelines recommend low-dose ASA in addition to therapeutic warfarin for patients with mechanical valves and for those with bioprosthetic valves who have risk factors. Warfarin is currently the mainstay of prophylactic therapy for mechanical valves, although stable, long-term anticoagulation is difficult especially in children because several medications are taken concomitantly and certain food may enhance or diminish the anticoagulant effect. In addition, the anticoagulant effect may be altered by intercurrent illness. Although enoxaparin (a LMWH) is an attractive alternative because of its ease in monitoring, to date, its use in prophylaxis for mechanical valves has been limited as an adjunct to bridge therapy when warfarin is stopped for an invasive procedure (184,186) and in pregnant women secondary to the teratogenic potential of warfarin (186–189).

Complete or near complete thrombosis of a prosthetic valve is a medical emergency, although small thrombi may result in no signs or symptoms. Infants are generally at higher risk of prosthetic valve thrombosis because of the smaller size of the prosthesis further complicated by the difficulties in achieving stable anticoagulation with warfarin therapy. Partial valve occlusion should be suspected in children with signs of low cardiac output, respiratory distress, hepatomegaly, pleural effusions, and/or pulmonary edema. Transesophageal echocardiography may reveal an increased inflow gradient across the valve and decreased leaflet mobility. Thrombi may be more

TABLE 75.5

Recommendations for Antithrombotic Therapy in Patients with Prosthetic Heart Valves

	ASA (75–100 mg)	Warfarin (INR 2.0–3.0)	Warfarin (INR 2.5–3.5)	No Warfarin
Mechanical prosthetic valves				
AVR—low risk				
<3 mo	Class I	Class I	Class IIa	
>3 mo	Class I	Class I		
AVR—high risk	Class I		Class I	
MVR	Class I		Class I	
Biological prosthetic valves				
AVR—low risk				
<3 mo	Class I	Class IIa		Class IIb
>3 mo	Class I			Class IIa
AVR—high risk	Class I	Class I		
MVR—low risk				
<3 mo	Class I	Class IIa		
>3 mo	Class I			Class IIa
MVR—high risk	Class I	Class I		

Depending on patients' clinical status, antithrombotic therapy must be individualized (see special situations in text). In patients receiving warfarin, ASA is recommended in virtually all situations. Risk factors: atrial fibrillation, left ventricular dysfunction, previous thromboembolism, and hypercoagulable condition. INR should be maintained between 2.5 and 3.5 for aortic disc valves and Starr-Edwards valves.

Modified from McAnulty JH, Rahimtoola SH. Antithrombotic therapy in valvular heart disease. In: Schlant R, Alexander RW, eds. *Hurst's The Heart*. New York, NY: McGraw-Hill, 1998:1867–1874(934).

AVR, aortic valve replacement; MVR, mitral valve replacement.

easily visualized with transesophageal echocardiography. Fluoroscopy is often used to evaluate valve motion and may be diagnostic as well. Therapy depends on the extent of the thrombus (clot burden) and the compromise to the patient. Small, nonobstructive thrombi are often managed with an increase in anticoagulation, close monitoring, and reevaluation. Thrombolytic therapy and/or operative exploration (thrombectomy or valve replacement) are required for larger thrombi resulting in hemodynamic compromise. Results of thrombolytic therapy in children mirror those in adults with an approximate 75% success rate and 25% incidence of complications including bleeding, thromboembolism, reoperation, and death (190–197). Management guidelines for valve thrombosis in children are taken from the adult experience and the reader is referred to the American College of Cardiology/American Heart Association Guidelines for Management of Patients with Valvular Heart Disease (114,184) and the American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition) (185,198).

ARRHYTHMIAS

Concerns for thrombosis in children with arrhythmias focus on three areas: atrial arrhythmias especially intra-atrial reentrant tachycardia/atrial flutter/atrial fibrillation, pacemakers/internal cardiac defibrillators, and electrophysiologic studies/catheter ablation procedures. Comprehensive practice guidelines for atrial fibrillation in adults were published in 2006 as a joint effort of the American College of Cardiology, American Heart Association, and the European Society of Cardiology (115). An extensive literature exists regarding arrhythmia and

pacemaker-related thrombosis in both adults and children and is beyond the scope of this chapter.

ACQUIRED HEART DISEASE

The two acquired heart diseases with known increased thrombotic risk are coronary involvement associated with Kawasaki disease and cardiomyopathy/myocarditis.

Kawasaki Disease

During the inflammatory phase of Kawasaki disease, two processes increase the risk of thrombus formation: vasculitis-induced endothelial injury to the coronary arteries and an increase in platelet quantity and activation. Later in the course, if coronary aneurysms form, especially giant coronary aneurysms 8 mm or greater, there is an increased risk of thrombus formation within the aneurysms secondary to low coronary blood flow velocities and relative stasis in addition to the endothelial injury and activated platelets. This risk is highest in the first 6 months of the disease. An extensive literature exists on the pathogenesis and natural history of Kawasaki disease and the diagnosis and management of thrombotic complications and is beyond the scope of this chapter (see Chapter 59). Recommendations for thrombosis prevention are outlined in the American Heart Association 2004 scientific statement, "Diagnosis, Treatment, and Long-term Management of Kawasaki disease: a Statement for Health Professionals from the Committee on Rheumatic Fever, Endocarditis and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association" (104) as well as in the 2008 American College of Chest Physicians

Evidence-Based Clinical Practice Guidelines, Antithrombotic Therapy in Infants and Children (199).

Cardiomyopathy/Myocarditis

Children and adolescents with cardiomyopathy including myocarditis are at risk for intracavitary thrombus formation secondary to stasis, regional wall motion abnormalities, endothelial dysfunction, and/or arrhythmias. The LV is the most common site although thrombi have been documented in the atria, right ventricle, systemic, and pulmonary vessels. Prevalence has been reported from 14% to 16% in moderate-sized pediatric series and thrombi have been identified in patients despite systemic prophylactic anticoagulation (112,113,200–204). Data are limited from which to generate management guidelines regarding antithrombotic prophylaxis, diagnosis, and treatment in the pediatric population. Limited guidelines are outlined in 2008 American College of Chest Physicians Evidence-Based Clinical Practice Guidelines, Antithrombotic Therapy in Infants and Children (199).

Cardiac Catheterization

The risk for thrombotic complications associated with cardiac catheterization is a known concern in pediatric cardiology that has generated a substantial literature and is beyond the scope of this chapter (see Chapters 12 and 13). The areas of major interest are thromboprophylaxis during diagnostic and interventional cardiac catheterization, postprocedure prophylaxis for intravascularly placed stents and occlusion devices, and management of catheterization-related vascular thrombosis.

Bridging Therapy

The question frequently arises concerning the discontinuation of anticoagulation in the event of an upcoming invasive procedure (operation, dental work, catheterization). Two factors should be considered: (a) the risk of thrombus during cessation of anticoagulation and (b) the potential of bleeding during the procedure (i.e., at what level of anticoagulation is the provider comfortable that the risk of bleeding will be acceptable). The options are as follows:

- Perform the procedure without interruption in anticoagulation. (Usually employed when the risk of bleeding is low.)
- Stop the warfarin 48 to 72 hours before the procedure (INR anticipated to fall to about 1.5). Restart the warfarin within 24 hours of the procedure without a heparin bridge. (Usually employed when the risk of thrombosis is low.)
- Stop the warfarin typically 48 hours before the procedure. Begin UFH when the INR falls below 2.0 and discontinue it 4 to 6 hours before the procedure. Restart heparin after the operation as soon as the risk of bleeding is determined to be low. Restart the warfarin and continue the heparin until target INR is reached. (Usually employed when the risk of thrombosis is high and the risk of bleeding during the procedure is also high.)

Guidelines for the management of warfarin during invasive procedures in *adults with prosthetic valves* is well established (184). Guidelines for the management of anticoagulation during invasive procedures in children with prosthetic valves as well as those anticoagulated for other reasons and with other agents (i.e., LMWH) have been extrapolated from these adult valve guidelines.

In an emergency situation when there is no time to wait for the INR to fall, the adult guidelines state that it is reasonable to give FFP prior to an invasive procedure in patients with a *mechanical valve* (class IIa, level of evidence B). These guidelines state that high-dose vitamin K should not be given to patients with a mechanical valve since a hypercoagulable state may be potentiated (class III, level of evidence B) (184,205).

Thrombolytic Therapy in Children and Adolescents with Heart Disease

Local and systemic thrombolytic therapy has been used extensively in children and adolescents with heart disease and thrombotic complications.

The strongest indication for thrombolytic therapy includes either a life- or limb-threatening thrombotic event. Significant bleeding (including intracranial hemorrhage) and thromboembolism are known complications of thrombolysis. The highest risk of bleeding from thrombolytic therapy is seen in preterm infants. When possible, the expertise of a pediatric hematologist should be sought. Contraindications to thrombolytic therapy need to be considered including active bleeding, an inability to maintain the platelet count $>75,000/\mu\text{L}$ or fibrinogen $>100\text{ mg/dL}$, a major surgery or site of hemorrhage within 7 to 10 days, seizures within 48 hours, central nervous system surgery/ischemia/trauma/hemorrhage within 30 days, preterm infant <32 weeks, or uncontrolled hypertension. While these contraindications are neither absolute nor evidence-based for every individual, the relative risks of thrombolytic therapy should be weighed against the potential benefits.

When instituting thrombolytic therapy, baseline laboratory values should be obtained (CBC, PT, PTT, fibrinogen, and D-dimer) prior to therapy and followed every 4 to 6 hours during therapy. An increase in the D-dimer and a drop in the fibrinogen level are indicative of a “lytic” state. To minimize the risk of bleeding, if the fibrinogen level drops below 100 mg/dL , consider either holding thrombolytic therapy or infusing cryoprecipitate as an external source of fibrinogen. The platelet count should be kept $>75,000/\mu\text{L}$. A head ultrasound should be obtained in all infants prior to thrombolytic therapy and FFP infusion should be considered to increase the infant’s plasminogen level (normally decreased in infants) to ensure the effectiveness of the thrombolytic therapy. Tissue plasminogen activator is currently the only thrombolytic agent available; Table 75.4 provides further information regarding mechanism of action and dosing. Concomitant low-dose heparin is often employed.

Future Directions

The Manuscript Oversight Committee of the American Heart Association has approved preparation of a scientific statement by an expert panel on the prevention and treatment of thrombosis in children and adults with CHD and in children with acquired heart disease (in review) (206). This statement includes an extensive review of thrombotic concerns in children and adolescents with single ventricle anatomy, prosthetic valves, arrhythmias, cardiac catheterization, and acquired heart disease (Kawasaki disease and cardiomyopathy/myocarditis) and includes graded recommendations based on currently available data. It is the anticipation of the writing group that this work will serve as a springboard for the much needed research on the etiology, risk factors, prevention, and treatment of thromboses in children and adolescents with heart disease.

Evaluation of Quality of Life in Children and Adolescents with Congenital and Acquired Heart Disease

Bradley S. Marino

Ultimately, the goals of pediatric research and clinical care are to maximize health and minimize symptomatology, disability, and dysfunction that may impact the lives of children with acute and chronic disease processes. Over the last several decades, new surgical techniques and advances in cardiopulmonary bypass, intensive care, interventional cardiac catheterization, noninvasive imaging, and medical therapies have significantly lowered neonatal mortality rates for children with the most complex congenital heart disease (CHD) (e.g., hypoplastic left heart disease) to <10% (1). In addition, cardiac-related mortality in patients with congenital and acquired heart disease has diminished significantly during the first two decades of life (2,3). Although survival rates vary by disease complexity, long-term survival (>20 years) rates for children with heart disease are estimated to be 95% for simple CHD, 90% for moderate CHD, and 80% for complex CHD in the current era (3).

Despite these advances, however, survivors suffer from morbidity resulting from their circulatory abnormalities and the medical and surgical therapies they have received. These morbidities significantly impact the child's neurodevelopmental (4–6), psychosocial (7–9), and physical (10–12) functioning and diminish their quality of life (QOL) (Fig. 76.1). Given the high incidence of functional impairment in the pediatric cardiac population, there has been a paradigm shift in clinical research from short-term mortality prevention to long-term morbidity assessment. As a result, outcome assessment focusing on QOL has become increasingly important in this high-risk population.

QOL may be described as a child's ability to function in situational contexts (family, school, and peer) and derive personal satisfaction from doing so (13–15). The multidimensional construct of QOL is thought to include three essential domains: physical health status and physical functioning, psychological status, and social functioning (Fig. 76.2) (13–15). QOL measurement provides a comprehensive description of an individual's health, may result in the identification of physical, functional, and psychosocial dysfunction, and is a critical component of the evaluation of long-term outcomes of chronic conditions and disease-specific therapies.

This paper delineates health measurement definitions including QOL and health-related QOL (HRQOL), identifies inherent difficulties in HRQOL measurement in the pediatric heart disease population, and discusses salient aspects of HRQOL instrument evaluation. In addition, it describes existing generic and disease-specific HRQOL measures that may be used to assess HRQOL in the pediatric heart disease population, what research on HRQOL in the pediatric heart disease population has shown, and the extent to which HRQOL evaluations are being fully utilized in clinical practice. Finally, a research and clinical agenda is proposed to harness the potential applications of HRQOL assessment.

HEALTH MEASUREMENT DEFINITIONS: QOL AND HRQOL

There are many ways to define “health.” While the differences in meaning between various attributes of health may be subtle, the differences are important and have significant implications as to how clinical and research data are interpreted and findings incorporated into how we care for children with chronic disease. *Health* has been defined by the World Health Organization as “a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity” (16). Indeed it was this initial definition of health that gave rise to the concept of QOL. *Health status*, which impacts QOL, may be thought of as a child's level of wellness versus illness, describing the impact of physiologic dysfunction, symptom burden, and/or level of illness control. Alternatively, *functional status* is defined as an individual's ability to perform activities of daily living, meet basic needs, fulfill roles, and maintain health and well-being within the context of various life situations (17). Functional status is often affected by health status and has a significant impact on QOL. However, it is HRQOL, a more specific description of QOL, which is the most relevant construct relative to clinical and research data assessing outcomes and the provision of comprehensive clinical care of children and adolescents with chronic illness or injury (18). *HRQOL* is defined as the influence of a specific illness, medical therapy, or health services policy on the ability of the patient to both function in and derive personal satisfaction from various physical, psychological, and social life contexts (19). For the purposes of this manuscript all references to QOL, hereafter, refer specifically to HRQOL.

Evaluating HRQOL is important because it allows for better communication among patients, parents, and health care providers; prioritization of problems based partially on patient and/or parent preference; the monitoring of changes over time or in response to a specific therapy; and screening for other significant physical and psychosocial problems (20). HRQOL measurement has emerged as a high priority not only for patients and their families and medical caregivers but also for the National Institutes of Health (NIH), Food and Drug Administration (FDA), and insurance providers (21). The NIH's Patient-Reported Outcomes Measurement Information System, part of the NIH Roadmap, is a multi-million dollar effort devoted in part to improving HRQOL (22–27). The FDA recognized the importance of such patient-reported outcomes by issuing guidance to industry on the use of such outcomes in clinical trials in support of medical product claims (28). A better understanding of the perceptions of HRQOL among patients with heart disease and their parents and health care providers may improve treatment and patient outcome (29,30) and enhance the ability to perform important

Figure 76.1. The relationship between heart disease-related morbidity factors and QOL. (From Marino BS, Uzark K, Ittenbach I, et al. Evaluation of quality of life in children with heart disease. *Prog Ped Cardiol* 2010;29:131–138, with permission.)

prospective cross-sectional, cohort, and randomized clinical trials to improve patient outcome. Despite the known advantages, assessment of HRQOL in the pediatric cardiac population is lacking.

Measurement of HRQOL in patients with congenital and acquired heart disease has been limited over the last 25 years. Moons et al. (31) noted that only 1 in 70 outcome studies published between 1980 and 2003 that purported to assess HRQOL in pediatric cardiac patients actually measured the patients' perceived HRQOL. In addition, more than half of the 70 articles did not meet any of the ten critical appraisal criteria for HRQOL research studies advocated by Gill and Feinstein in JAMA in 1994 (32). The lack of rigorous research on HRQOL in the pediatric heart disease population is not surprising given the inherent difficulties of measuring HRQOL in this population.

INHERENT DIFFICULTIES OF HRQOL EVALUATION IN THE PEDIATRIC HEART DISEASE POPULATION

HRQOL assessment in the pediatric population is challenging due to the wide age range and the changing developmental capabilities of the patients as they age. HRQOL assessment in the pediatric cardiac population is further complicated by the

variety of congenital and acquired diseases, varying levels of severity, the array of therapeutic modalities that may be utilized to treat the patient (medical, surgical, and interventional), and the spectrum of outcomes. Similar to other pediatric chronic diseases, there may be variation in the perceived impact of heart disease on HRQOL, since many of the patients have always had heart disease (as in CHD) while others have been diagnosed with heart disease at an age when they were aware of the acute change in their health status (as in acquired heart disease).

Patient–family interactions are critical in QOL assessment, and the role of proxy reporting (parent/guardian) and cross informant variance is often debated (33). It has been extensively documented that HRQOL measurement in children with chronic health conditions and healthy children provided by proxy respondents is not equivalent to that reported by the child (34,35). These findings indicate that proxy reports cannot be substituted for child self-reports (36) and evaluations of pediatric cardiac patients' perspectives regarding treatment outcome should be included in pediatric clinical care and clinical trials given the documented differences between child and proxy reports. While pediatric patient self-report should be considered the standard for measuring patient-perceived HRQOL (37), there may be situations when the child is too young, too cognitively impaired, or too ill to complete an HRQOL instrument, and proxy reporting may be required. Further, it is typically parents' perceptions of their child's HRQOL that influences health care use (38,39). Ideally, parent and child QOL instruments that measure the perspectives of both the child and proxy reporter with the same constructs and parallel items to make comparisons between self and proxy reports more informative and useful should be chosen (40). As noted by Moons et al. (31) most research studies assessing HRQOL in children with heart disease have only assessed proxy reporters (parents/guardians) and ignored the HRQOL perceptions of the child. Studies of the cognitive development in children, psychometric studies on pediatric QOL measures that have included child self-reporting, and cognitive interviewing studies on children's abilities to respond to questionnaires indicate that self-reports from children over 7 years of age are reliable and valid (41). Both patients and their parents provide important information, even though they may vary or even disagree significantly with one another. It may be that understanding the differences in perception of HRQOL between patients, their parent/guardians, and medical caregivers is more important and informative than perceived agreement (30).

In addition to assessment issues related to the pediatric population in general and the pediatric heart disease population specifically, issues related to cultural and demographic variables (culture, race, ethnicity, income) affect HRQOL assessment in both pediatric and adult respondents. Culture, race, ethnicity, and income have critical influences on HRQOL measurement relative to the values that are attributed to various

Figure 76.2. Definition of quality of life. (From Marino BS, Uzark K, Ittenbach I, Drotar D. Evaluation of quality of life in children with heart disease. *Prog Ped Cardiol* 2010;29:131–138, with permission.)

health states by children and their parents, the language in which health is described by children and their families, and the perceived functional impact of symptoms and changes in health states (42).

HRQOL INSTRUMENT EVALUATION

When measuring HRQOL, it is important to be clear on whether the goal of the application is to assess HRQOL, functional status, or both. These measures of health are distinct constructs and are often confused with each other; note prior definitions. When assessing either HRQOL or functional status for research and clinical application, specific aspects of instrument selection (Tables 76.1 and 76.2), validation (Table 76.3), and availability (Table 76.4) must be considered.

When selecting an instrument, it is important to note the instrument type, the specific construct that will be assessed, desired respondent type(s), patient and proxy reporter age range(s), and the domains to be assessed (Table 76.1). When selecting a specific form from within an instrument grouping, the number of items in the tool and the average completion time should be considered as it may impact the feasibility of completing the research project or clinical application (Table 76.2).

Both generic and disease-specific instruments exist that may be used to measure HRQOL or functional status in the pediatric heart disease population (43–49). Whether generic or disease specific, the “ideal” QOL measure will have a patient self-reporting mechanism with parent/guardian proxy reporting and a wide age range, be easily self-administered in a reasonable timeframe, and have an array of relevant constructs to describe and measure HRQOL or functional status. Generic HRQOL or functional status measures assess these constructs in both healthy children and in children with chronic disease. They may be used to compare various chronic disease groups or chronic disease groups and healthy controls. Disease-specific instruments assess HRQOL in a particular condition or disease, may be more comprehensive for a specific disease, and may be a better discriminator of differences between subgroups within a disease category. Disease-specific pediatric cardiac HRQOL instruments may provide new, critical information on the outcome of present and future interventional catheterization and cardiac surgical procedures in the short and long term and may be utilized for randomized clinical trials for cardiovascular drugs and new technologies and interventions. In addition, a disease-specific pediatric cardiac HRQOL instrument may define changes in HRQOL over time (evaluative tool), predict future changes in HRQOL (prognostic tool), and signal new problems or issues that might not be noted by traditional biologic markers (diagnostic tool).

Assessing prior validation data on a given HRQOL or functional status instrument is central to the instrument evaluation process (Table 76.3). When assessing validation of a given instrument, four specific questions relative to the psychometric properties of the instrument should be asked: (a) *Has the instrument been shown to be reliable in the patient population being studied?*, (b) *Has the instrument been shown to be internally valid in the patient population being studied?*, (c) *Has the instrument been shown to be externally valid in the patient population to be studied?*, (d) *If the study is assessing change over time or the impact of an intervention, has the instrument been shown to be responsive in the patient population to be studied?*

All psychometric instruments must be shown to be reliable before validity and responsiveness may be considered (50). An “unreliable instrument” cannot be deemed valid or responsive. Demonstrating reliability involves assessing score “reproducibility” through internal consistency measurement (Cronbach α)

and comparing scores on the same patient at two distinct points in time with an appropriate interval between them to minimize recall bias (test–retest reliability). Validity testing of a psychometric scale is an ongoing, evidence-based process that assesses the degree of confidence that one should have in inferences made about a test taker based on their score. Assessing validity is often divided into the domains of “internal” and “external” construct validity (51–53). “Internal validity” (50–52,54) may be thought of as an assessment of content validity and structural validity, which includes assessment of the theoretical conceptualization of the respective instrument; the clarity, relevance, and representativeness of the item content; and tool construction. In contrast, establishing “external validity” requires demonstrating convergent and discriminant construct validity and “generalizability” (51,52,55). “Generalizability” may be defined as the ability of a tool to provide valid and reliable information when utilized in different geographic regions and patient populations (52). Generalizable tools allow researchers to have confidence that data collected from multiple sites and regions are comparable. Substantiation of the “generalizability” part of external validity enables a HRQOL instrument to be used for clinical applications and multicenter research that may serve as a platform for future multisite cross-sectional and prospective studies using HRQOL as an outcome. Responsiveness describes the ability of the HRQOL or functional status instrument to be sensitive to change in score after intervention or if there is meaningful change in score over time (50). Having a responsive instrument allows the investigator to note differences in HRQOL based on a specific intervention or treatment strategy, which is critical to assessing all potential interventions in a given disease population. In addition, a responsive tool will allow the clinician or researcher to see changes in HRQOL over time as a patient’s health status or functional status worsens. Having a responsive instrument is critical to any interventional agenda or follow-up program for any given chronic disease population.

EXISTING GENERIC AND DISEASE-SPECIFIC HRQOL MEASURES THAT MAY BE USED TO ASSESS HRQOL IN THE PEDIATRIC HEART DISEASE POPULATION

Both the PedsQL 4.0 Cores scales, a generic HRQOL measure, and the Child Health Questionnaire (CHQ), a generic functional status measure, have patient and proxy reporting, wide age range, and may be administered in a reasonable timeframe. In addition, these commercially available tools have been shown to be reliable and internally and externally valid, and responsive in the United States and many other countries after language translation (Tables 76.1 through 76.4) (43,44). Five disease-specific pediatric cardiac HRQOL instruments have been previously described (45–49). The CHD-TNO/AZL Adult QOL (CHD-TAAQOL) questionnaire is a disease-specific instrument that assesses HRQOL in young adults with CHD (45). The PedsQL 3.0 Cardiac Module (46), Congenital Heart Adolescent and Teenager Questionnaire (CHAT) (47), ConQOL (48), and Pediatric Cardiac Quality-of-Life Inventory (PCQLI) (49) measure HRQOL in the pediatric cardiac population. Instrument availability (form specific authorization requirements, user costs, and available language translations) are shown in Table 76.4. The PedsQL 3.0 Cardiac Module (46), created and validated by Uzark et al. at a single site, was a critical and important step forward in the objective assessment of HRQOL in children with heart disease. The PedsQL 3.0 Cardiac Module has been shown to be reliable, internally and externally valid. The 27-item PedsQL Cardiac Module encompasses six Scales: Heart Problems and Treatment;

TABLE 76.1 Instrument Selection: Constructs, Respondent Types, and Domains

Instrument Type	Instrument	Construct Measured	Respondent Type	Age Range (years)	Domain(s)
Generic	CHQ (43)	Functional status	Self-report Proxy report ^a	10–18 5–18	Physical functioning, Role/Social emotional, Role/social behavioral, Role/social physical, Bodily pain, General behavior, Mental health, Self-esteem, General health perceptions, Change in health, Family activities, Family cohesiveness, Parental impact-time, Parental impact-emotional ^b
	PedsQL 4.0 General Core Scales (33)	HRQOL	Self-report Proxy report	5–7, 8–12, 13–18, 19–25 2–4, 5–7, 8–12, 13–18	Physical, Emotional, Social, School ^c
	CHAT (47)	HRQOL	Self-report	11–18	Physical symptoms, Physical limitations, Limitations of physical education at school, Social limitations, External pressures, Concerns (general, social, educational, physical, total)
Disease-Specific (CHD)	ConQol (48)	HRQOL	Self-report	8–11, 12–16	Symptoms, Activities, Relationships, Coping and control ^d
	CHD-TAAQOL (45)	HRQOL	Self-report	17–32	Symptoms, Impact cardiac surveillance, Worries
	PCQLI (49)	HRQOL	Self-report Proxy report	8–12, 13–18 8–12, 13–18	Disease impact (physical) Psychosocial impact
	PedsQL 3.0 Cardiac Module (46)	HRQOL	Self-report Proxy report	5–7 ^e , 8–12, 13–18 2–4, 5–7, 8–12, 13–18	Heart problems (symptoms) Treatment (barriers) Perceived physical appearance Treatment anxiety Cognitive problems Communication

^aProxy reports are for parents, guardians, or primary home care providers of patients.

^bThe CHQ domain lists include both those for the patient and proxy reporter. Domain differences between patient and proxy report forms include the Parental Impact-Time, and Parental Impact-Emotional domains may only be found in the proxy form; the domains Role/Social-Emotional and Role/Social-Behavioral from the self report form are combined into one domain, Role/Social Emotional/Behavior in the proxy form; the listed domains except for Change in Health, Family Activities, and Family Cohesiveness create the Physical and Psychosocial summary scores for the Proxy Report Forms (CHQ-PF50 and CHQ-PF28) only.

^cThe Physical domain makes up the Physical Health Summary Score, while the Emotional, Social, and School domains make up the Psychosocial Summary Score.

^dFor adolescents 12–16 years old only.

^eReliability of the PedsQL 3.0 Cardiac Module Young Child self-report Form for ages 5–7 years has not been established (ranged from 0.35 to 0.83).

Treatment II, Perceived Physical Appearance, Treatment Anxiety, Cognitive Problems, and Communication (46,56). The PedsQL 3.0 Cardiac Module has not yet been shown to be generalizable to other geographic regions or demographic populations in the United States. The CHAT and ConQol questionnaires have important limitations that include intended for use in heart disease patients with CHD only (47,48), narrow age range (47,48), lack of parent proxy reporting (48), no generalizability data to support broad applicability to other geographic regions or demographics within the United States (47,48), and/or an inadequate ability to discriminate among various types of cardiovascular disease across a wide age range (48). The PCQLI is the most recently published disease-specific instrument. Similar to the PedsQL 3.0 Cardiac Module, it has a patient self-reporting mechanism with parent/guardian proxy reporting, wide age range, is easily self-administered in a reasonable time frame, and has an array of relevant constructs to describe and measure HRQOL in the pediatric heart disease population. The PCQLI is the only disease-specific measure that has been tested in a multicenter trial and shown to be

reliable, valid, and generalizable in the United States (57,58). The ConQol and PedsQL 3.0 Cardiac Module can distinguish among disease severity subgroups but only within select subsets of a study population (age, respondent type) (46,48). In contrast, PCQLI Total and subscale scores (Disease Impact and Psychosocial Impact) differentiate between CHD severity subgroups irrespective of age category, score examined, or respondent type (40). From a research perspective, this is an important development that will facilitate cross-sectional and prospective studies of HRQOL in clinically important subgroups in the pediatric heart disease population. It is important to note that none of the five disease-specific instruments have been shown to be responsive in the United States.

In summary, whether selecting a measurement tool for research or clinical application it is critical to define the specific hypothesis or what clinical information is desired and then match the hypothesis/clinical data requirement to potential instruments based on the constructs assessed in the specific instrument, the respondents desired, and the feasibility of utilization. It is important to use age-appropriate measures

that reflect the maturity and the cognitive development of the desired respondents. It is vital that the instrument being considered for measurement be reliable, valid, and responsive in the patient population being considered. The instrument needs to have been shown to be responsive if assessing change in score over time or after intervention in the population being studied. It is important to collect data from both patient *and* parent/guardian proxy respondents to identify the full HRQOL impact on the patient, parent, and family. Finally, it is important to use both a disease-specific and generic measure, to allow discrimination between subgroups and comparison with other chronic disease groups and/or healthy children.

RESEARCH ON HRQOL IN PEDIATRIC PATIENTS WITH HEART DISEASE: WHAT IS KNOWN

HRQOL Studies in the General Congenital Health Disease Population

Most early outcome studies in patients with CHD described mortality and morbidity or health status, including anatomic or hemodynamic outcome, electrophysiologic sequelae, and/or exercise capacity following surgical interventions or included “QOL” parameters such as marital status, number of offspring,

employment status, or educational attainment in adults with CHD (59). More recent studies have recognized the multidimensional nature of HRQOL and have included not only physical health status and physical functioning but also psychological status and social functioning. Unfortunately, there are only a few studies that have evaluated the patient's self-perceptions of HRQOL.

Health Status and Functional Status in the Heart Disease Population

In children with CHD as young as one to three years, Limpopoulos et al reported a high incidence of functional limitations including difficulties in socialization skills (11). Walker et al. (60) evaluated functional status in children attending a cardiology clinic, utilizing the CHQ (CHQ PF-50) to describe the physical and psychosocial health status by parent-proxy report. The sample of children seen in the out-patient cardiology clinic was reported to have worse physical functioning, general health perception, assessment of family activities, and parental emotional impact, as well as more anxiety problems and learning problems. Majnemer et al. (61) used the CHQ PF-50 as well as the Child Behavior Checklist and the Parenting Stress Index in describing well-being in children 5 years of age following open heart surgery in infancy. Mean scores on the CHQ were in the normal range; however, parents

more often reported problems related to anxiety, attention, developmental delays, and learning. The child's psychosocial health status was significantly correlated with parental stress. Both of the later studies acknowledge parental responses are likely to be influenced by their hopes and expectations for their child and how well they are coping as a family. This is consistent with one of the earliest studies of the emotional adjustment of children with CHD by DeMaso and colleagues, (62) who found that approximately 33% of the variability in the child's adjustment was accounted for by maternal perceptions, while medical severity accounted for <3% of the variability.

HRQOL in the Heart Disease Population

Self-reported HRQOL related to physical health, psychosocial health, social functioning, and school functioning for children with CHD is reduced compared to healthy children (Fig. 76.3A,B) (56,57,63,64). Mussatto et al. (64) found that the greatest negative impact on HRQOL was reported in the areas of social and educational functioning, despite the perception that CHD primarily has physical effects. In a large single-center study of HRQOL in children with heart disease, Uzark et al (56) evaluated both parent proxy and self-reported perceptions utilizing the PedsQL 4.0 Core scales. As perceived by parents, worse physical and psychosocial HRQOL is related

Figure 76.3. A: PedsQL generic HRQOL measure—Child. B: Adolescents with CHD have lower PedsQL scores than healthy controls. Lower PCQLI scores are associated with increasing severity of CHD in children and adolescents. *Significant difference when compared to healthy controls, determined by t-test. **Significant difference among disease severity categories, determined by one-way analysis of variance. (From Marino BS, Tomlinson R, Wernovsky G, et al. Validation of the pediatric cardiac quality of life inventory. *Pediatrics* 2010;126:498–508, with permission.)

to the severity of heart disease. While most children with heart disease reported good overall HRQOL, 20% of the children with heart disease reported significantly impaired psychosocial HRQOL, including children with mild or repaired heart disease. A recent systematic review of studies assessing psychological adjustment and HRQOL in children and adolescents following open heart surgery for CHD (63) concluded that studies on self-reported psychological adjustment indicate a good outcome; however, according to their parents, a considerable proportion of children experienced psychological maladjustment, which was related to severity of CHD and developmental delay.

The largest multicenter study assessing HRQOL in the United States utilizing a reliable, valid, and generalizable disease-specific HRQOL measure including both child and adolescent self-report and parent/guardian-proxy report was performed by Marino et al. in the PCQLI Validation Study (40). In this study 1,605 patient–parent pairs (3,210 total respondents) participated from seven geographically diverse centers in the United States. In this study, heart disease patients with both CHD (68% of the cohort) and acquired heart disease (32% of the cohort) were included. This study showed that lower patient and parent-reported HRQOL scores were associated with higher disease severity (Fig. 76.4) and increased medical care utilization (Fig. 76.5), poorer patient self-perception and competency, and increased behavioral and emotional problems in the pediatric heart disease population (Table 76.5). PCQLI scores (Total, Disease Impact, and Psychosocial Impact) differed significantly among disease severity subgroups (mild CHD, biventricular CHD s/p surgical repair or palliation, and single ventricle CHD s/p Fontan completion) (Fig. 76.4). Mild CHD was defined as CHD that had not required surgical or catheter-based intervention. Furthermore, patients in the repaired biventricular subgroup had significantly lower PCQLI Total and subscale scores than patients in the mild subgroup, and patients in the palliated single-ventricle subgroup had significantly lower PCQLI Total and subscale scores than patients in both the repaired biventricular and mild CHD subgroups (Fig. 76.4). These results were reproducible across all age categories and respondent types and are consistent with

widespread clinical observations that increased disease severity is associated with a lower HRQOL. Increased number of cardiac surgeries, cardiac-related hospital admissions, and doctor visits in the last 12 months were associated with lower PCQLI Total score (Fig. 76.5). These results were consistent across all four forms (Child Form, Parent of Child Form, Adolescent Form, and Parent of Adolescent Form). Worse PCQLI Total score was significantly correlated with lower Global Self-Worth score on the Self Perception Profile for Children and Adolescents for both age groups (Table 76.5). A statistically significant positive correlation was noted between the PCQLI Total score and Achenbach (Youth Self Report and Child Behavior Checklist) Total Competency score, and statistically significant inverse correlations existed between PCQLI Total score and both the Achenbach Internalizing Problems summary scale score and DSM-IV Oriented Scale scores (Affective Disorder, Anxiety Disorder, Somatic Disorder, Attention Deficit Hyperactivity Disorder) for all groups (Table 76.5) (40).

Interestingly, there was significant variation noted in the specific diagnosis and procedural groups (Table 76.6) for acyanotic two-ventricle (e.g., aortic stenosis), cyanotic two-ventricle (e.g., tetralogy of Fallot) and the palliated single-ventricle Fontan populations (40). While each specific population group segregated into a particular HRQOL score range (aortic stenosis—80s; tetralogy of Fallot—70s; and Fontan—60s) based on the underlying disease severity and the medical, catheter-based, and surgical therapy required, there were complex single-ventricle Fontan patients who had HRQOL scores as high as aortic stenosis patients who had not undergone intervention and aortic stenosis patients who had undergone intervention who had HRQOL scores that were worse than the typical Fontan. These data suggest that there are resilience and depressant factors that increase or decrease each individual patient's arc of HRQOL over time (Fig. 76.6). Understanding broad resilience and depressant factors across the entire heart disease population and/or resilience and depressant factors important for specific diagnosis or procedural groups will create opportunities to prevent the development of lower HRQOL or treat heart disease patients with lower HRQOL to improve it.

Figure 76.4. Association of severity of congenital HD with PCQLI scores. Values are expressed as means, with error bars representing SEMs. All three-way ($p < 0.001$) and two-way ($p \leq 0.036$) comparisons were statistically significant. BV indicates repaired biventricular HD subgroup; SV, palliated single-ventricle subgroup; mild, mild HD subgroup. (From Marino BS, Tomlinson R, Wernovsky G, et al. Validation of the pediatric cardiac quality of life inventory. *Pediatrics* 2010;126:498–508, with permission.)

Figure 76.5. Lower PCQLI scores are associated with increasing medical care utilization in children and adolescents. Variation of PCQLI total scores with medical care utilization factors. Values are expressed as means, with error bars representing SEMs. All comparisons were significant ($p < 0.001$). (From Marino BS, Tomlinson R, Wernovsky G, et al. Validation of the pediatric cardiac quality of life inventory. *Pediatrics* 2010;126:498–508, with permission.)

HRQOL Studies in Specific Heart Disease Subgroups

HRQOL and functional status have also been studied in some specific patient subgroups with heart disease. In children with transposition of the great arteries (TGA), Culbert et al. (65) from the Congenital Heart Surgeons Society assessed

functional status using the CHQ-CF87 completed by 306 children 11 to 15 years after TGA repair. Health status was perceived as excellent when compared with published normative data and was better after arterial switch operation (ASO) than after atrial switch operation. Dunbar-Masterson et al. (66) who used the parent version of the CHQ also found that at 8 years

TABLE 76.5

TABLE 76.6

Variation in PCQLI Scores (Median and Range) Within Specific CHD Diagnosis and Procedural Groups

	PCQLI Median Total Score (Range)			
	Child	Parent of Child	Adolescent	Parent of Adolescent
AS (<i>n</i> = 75)	86.2 (51.9, 100)	86.8 (54.1, 100)	89.5 (65.1, 97.8)	85.2 (40.8, 99.3)
TOF (<i>n</i> = 125)	75.6 (48.7, 100)	78.6 (43.5, 100)	79.6 (39.6, 99.3)	78.7 (33.5, 100)
Fontan (<i>n</i> = 219)	64.4 (32.2, 99.1)	66.1 (30.7, 100)	70.5 (39.6, 100)	69.7 (26.0, 98.5)

AS, Aortic Stenosis; TOF, Tetralogy of Fallot.

From Marino BS, Tomlinson R, Wernovsky G, et al. Validation of the Pediatric Cardiac Quality of Life Inventory. *Pediatrics* 2010;126:498–508, with permission.

of age, children had an overall physical and psychosocial health status after the ASO similar to that of the general population. It was also noted that lower IQ and academic achievement were associated with worse psychosocial health status. Hovels-Gurich et al. (67) reported that children with TGA who had undergone neonatal ASO had parent-reported behavioral impairment at age 8 to 14 years with normal self-reported HRQOL.

Brosig et al. (68) compared psychosocial outcomes between preschool-aged survivors who underwent ASO for TGA and Fontan palliation for hypoplastic left heart syndrome (HLHS). By parent report, HRQOL scores in both CHD subgroups did not differ from healthy controls. Parents of children with HLHS reported more negative impact of the child's illness on the family and more parenting stress than parents of children with TGA. Children with HLHS had higher rates of attention and externalizing behavior problems than children with TGA. In a large study of Fontan survivors (69) 6 to 18 years of age, parents reported CHQ functional status summary scores that were significantly lower than the US population for Physical Functioning and Psychosocial Functioning. Parent-reported patient conditions, including behavior, learning, anxiety, attention problems, and depression explained the greatest amount of variation in the Psychosocial Functioning scores.

In a study by DeMaso et al. (70) HRQOL has been assessed in children and adolescents with implantable cardioverter-defibrillators. While the parent-reported psychosocial summary scores for children with defibrillators were not significantly different from the normative U.S. sample, the domains of social emotional behavioral roles, self-esteem, and the emotional impact of their child's health on themselves were all significantly lower than the normative sample. A recent multicenter study by Czosek et al. (71) compared HRQOL scores between pediatric device patients and healthy controls, and determined the key drivers of HRQOL in pediatric device patients. The study included 173 patient–parent pairs (40 implantable cardiac

defibrillators [ICD]/133 pacemaker; 50% CHD; 50% male; median age 13 [8 to 18] years). Compared to healthy controls, both patients and parents reported significantly lower PedsQL Total scores. ICD patients had significantly lower PCQLI Total scores than pacemaker patients. CHD patients had significantly lower PCQLI Total score than non-CHD patients. The key drivers of patient HRQOL were presence of ICD, CHD, and worse self-perception. For parent proxy reporters, patient HRQOL was driven by internalizing behavioral problems (anxiety, depression, and somatization). Interestingly, activity restrictions and device complications did not impact HRQOL. Whether these factors can be mitigated through the use of psychological interventions needs to be assessed.

Finally, in the pediatric heart transplant population, using the Children's Global Assessment Scale, 27% of children 6.1 to 12.9 years after transplant had emotional adjustment difficulties (72) and there was a significant correlation between emotional adjustment and family functioning. Wray et al. (73) also found that a significant number of pediatric heart transplant recipients (>33%) had increased behavior problems and diminished social competence, especially in children with a pretransplant diagnosis of CHD in comparison to children with cardiomyopathy pretransplant.

Predictors of HRQOL in the Pediatric Heart Disease Population

Neurodevelopmental Predictors of HRQOL in the Pediatric Heart Disease Population

Few studies have investigated the impact of neurodevelopmental outcome on HRQOL in the pediatric CHD population. For children with TGA, Dunbar-Masterson et al found that lower full-scale IQ (intelligence) and lower performance in reading and math (academic achievement) were associated with lower parent-reported psychosocial HRQOL scores at eight years of age (66). Williams et al. (74) found that children with Fontan palliation for HLHS displayed significant delays in communication and motor skills and lower parent-reported psychosocial HRQOL scores. Of note, both of these studies used a generic QOL instrument to measure psychosocial QOL, which may not be as sensitive or accurate as a disease-specific instrument (75). In addition, neither study measured patient-perceived HRQOL or specifically assessed the association between neuropsychological impairments and patient-perceived HRQOL. Parent-reported and self-reported HRQOL are both important since perception of HRQOL differs between patients and parents (30,56).

The cardiac-specific module of the PedsQL includes a cognitive problems subscale and a communication subscale (44,46). Using the PedsQL cardiac-specific module, Uzark et al. (56)

Figure 76.6. Patient independent arc of HRQOL: resilience versus depressant factors.

found that children with severe cardiovascular disease have lower parent-reported and self-reported HRQOL scores on the cognitive problems subscale and lower parent-reported HRQOL scores on the communications subscale than children with less severe cardiovascular disease. Recently, Marino et al. (76) demonstrated that worse executive functioning, gross motor ability, and mood (presence of anxiety and depression) significantly predicted lower PCQLI score after controlling for patient demographics and important clinical covariates. Executive functioning, gross motor ability, and mood accounted for up to 50% of the variance in patient and parent-reported HRQOL scores. These factors appear to be key drivers of HRQOL in complex CHD survivors and may be targets for future intervention (76).

Psychosocial Predictors of HRQOL in the Pediatric Heart Disease Population

While multiple studies have shown that there is psychosocial dysfunction in the pediatric heart disease population, few studies have assessed association between psychosocial predictors in the individual or family environment and HRQOL (56,57,69,77–79). A recent multicenter multinational study in the United States and England completed by Marino and colleagues explored the relationships between heart disease complexity, HRQOL, and psychosocial morbidity factors. Eight hundred and fifteen patient–parent pairs participated in the study with a mean patient age of 12.5 ± 1.5 years. The study assessed the mediating impact of specific psychosocial morbidity factors (family functioning and parental stress, and patient and parent posttraumatic stress and trait anxiety) on the association between heart disease complexity and lower HRQOL. High complexity was associated with a lower PCQLI Psychosocial Impact subscale score. Higher parental stress, posttraumatic stress, and trait anxiety scores were associated with a lower PCQLI Psychosocial Impact subscale score. The association between high complexity and lower PCQLI PI score was mediated by worse parental stress, posttraumatic stress, and trait anxiety (Total Correlation [direct and indirect effects] = -0.21 to -0.46 ; $p < 0.001$) for both patients and parents. Interventions on these psychosocial morbidities may improve QOL (80).

SUMMARY

Many studies of HRQOL in children with CHD have been limited by small sample size, have often relied on parental proxy report of the child's HRQOL, reported health status or observed functional status, or focused on a single dimension of HRQOL. Recent instrument development has allowed multidimensional, self-report of HRQOL, essential to development of interventions to improve HRQOL. Further research is needed to discover links between specific aspects of neurodevelopmental and psychosocial morbidity factors and HRQOL to identify developmental delays and psychosocial issues that may be improved through intervention. By characterizing the relationship between disease complexity, neurodevelopmental and psychosocial morbidity and HRQOL, physicians and caregivers will be able to change the medical care delivery system to significantly improve the lives of children with CHD and ensure their future success.

CLINICAL IMPLEMENTATION (IS HRQOL EVALUATION UTILIZED IN CLINICAL PRACTICE?)

The importance and utility of HRQOL assessment with reliable, valid, generalizable, and responsive instruments in the

pediatric heart disease population is centered on the fact that they provide a means to improve patient HRQOL outcomes through (a) the improvement of comprehensive follow-up of the pediatric heart disease population (surveillance and screening), (b) the identification of at-risk patients (risk stratification of heart disease subpopulations), (c) the identification of modifiable risk factors to prevent adverse outcomes (prevention), and (d) the design of interventions for children with poor outcomes (treatment planning). Early identification of neurodevelopmental impairments in academic achievement, language, visual construction and perception, attention, processing speed, memory, executive functioning, fine and gross motor skills, and/or attention deficit hyperactivity disorder (ADHD) in these children may allow the clinical care team to stratify populations and improve HRQOL outcomes through targeted intervention for at-risk children. Given some of the early data on the utility of physical rehabilitation in patients with CHD and diminished exercise capacity, physical functioning and HRQOL may be improved through rehabilitation or medical or device-based (pacemaker) therapies. In addition, early identification of psychosocial functioning issues in the child and/or family (posttraumatic stress, trait anxiety, depression, coping, family functioning, and parental stress) may allow risk stratification and the incorporation of targeted interventions to prevent or treat psychological or social morbidity. Unfortunately, the clinical evaluation of neurodevelopmental impairments and physical and psychosocial morbidity on HRQOL in children with heart disease has not become a standard component of care and much is to be learned. The clinical utility of current instruments is largely unknown.

Multiple barriers exist to incorporating HRQOL assessment into the clinical environment (19). Pediatricians and cardiologists (medical home providers) have ever-increasing demands on their time and the utilization of HRQOL instruments for surveillance and screening will only occur if administration, scoring, and interpretation of measures are simple and are easily integrated into the clinical practice setting in “real-time” as part of the “paper” or electronic medical record. In addition, practitioners will only incorporate HRQOL assessment into their clinical care if there is compelling evidence that surveillance, screening, referral, evaluation, and intervention are efficient, cost-effective, and make a difference in patient-specific HRQOL outcomes. One of the biggest barriers to incorporation is the lack of knowledge among practitioners of the theoretical benefits to HRQOL assessment. Only through clinical research studies focusing on harnessing the potential of HRQOL assessment will these barriers begin to fall.

RESEARCH AGENDA (WHAT IS NEEDED IN HRQOL RESEARCH IN PEDIATRIC HEART DISEASE PATIENTS?)

1. Future HRQOL research should focus on the associations of specific morbidities/phenotypes in the pediatric heart disease population and HRQOL to determine candidate factors for interventional studies for *prevention* and *treatment*. Specifically, further research is needed to discover links between neurodevelopmental, psychosocial, and physical morbidity factors and HRQOL to identify specific functional deficits that may be prevented or mitigated through intervention.
2. Both patient and parent respondents need to be evaluated in HRQOL research to learn more about similarities and differences between patient and parent respondents. These patterns will inform clinical applications on how best to assess HRQOL in patients and their parent/guardians and

inform how future screening and interventions programs may improve HRQOL.

3. It must be demonstrated that HRQOL assessment in the clinical setting will ultimately result in clinically meaningful changes in HRQOL and/or functional status. Specifically, it must be demonstrated that (a) it is feasible to collect HRQOL data in “real-time” in the clinical setting and that patients may be stratified into low- and high-risk groups for neurodevelopmental, physical, and psychosocial dysfunction, (b) it is feasible to refer patients with lower HRQOL scores stratified into a high-risk category into interventions, and (c) interventions in a high-risk group will result in clinically meaningful changes in HRQOL.
4. A responsive instrument is required and fundamental for the field to pursue an interventional agenda that will improve current clinical practice. Efforts should be made to demonstrate responsiveness in disease-specific measures shown to be reliable, valid, and generalizable in the United States. Once responsiveness has been demonstrated, this HRQOL tool should be considered for inclusion in all randomized clinical or interventional drug, device, or surgical treatment trials, where appropriate.
5. New HRQOL instruments should be developed for aging cohorts of pediatric heart disease patients (young adults and adults) in the United States as there is a rapidly growing population of Adult with CHD (ACHD population) in transition with changing HRQOL assessment needs. HRQOL instruments for adults with heart disease are intended for patients with heart disease due to hypertension or coronary ischemia. A combination of an adult generic HRQOL measure and an ACHD disease-specific HRQOL measure will provide the necessary tools to provide critical information on this unique and growing population.

CLINICAL AGENDA (WHAT IS NEEDED TO HARNESS THE POTENTIAL OF HRQOL ASSESSMENT FOR CLINICAL USE IN PEDIATRIC HEART DISEASE PATIENTS?)

1. Begin incorporating HRQOL evaluation into the clinic visit to take full advantage of the current advances in HRQOL measurement.
2. Strive to make all HRQOL evaluations conducted in clinical settings “research quality” (or at least create standard evaluation protocols) so that the field may benefit from reliable, valid, and potentially generalizable clinical information. There is so much variability in the way evaluations are presently conducted that it makes it difficult to generalize any data collected at any particular site or clinical setting across settings and/or populations.
3. Once it has been demonstrated that HRQOL assessment may be used for neurodevelopmental, psychosocial, and physical morbidity risk stratification, HRQOL assessment should be performed in all out-patient clinic visits as part of a formal standardized surveillance and screening program to allow for referral, intervention, and follow-up.

CONCLUSION

Over the last several decades mortality rates for children with heart disease have fallen. However, survivors may have neurodevelopmental, psychosocial, and physical morbidities that lower HRQOL. Although HRQOL assessment in this high-risk population has been lacking due to inherent issues in

HRQOL assessment in the pediatric heart disease population, advances have been made in HRQOL measurement with new reliable, valid, and generalizable measures. These questionnaires may be utilized to rapidly improve HRQOL research and obtain critical information that may be translated into the clinical domain. Rigorous characterization of the relationship between neurodevelopmental, psychosocial, and physical morbidity factors and HRQOL will identify specific factors amenable to intervention and allow clinicians to modify the medical care delivery system to significantly improve the lives of children with CHD and promote their future success. Formal screening and intervention programs based on HRQOL assessment will allow clinicians to intervene in the case of those children with significant deficits with the greatest potential to improve HRQOL.

INTRODUCTION

Much of the science of quality, safety, and continuous quality improvement (QI) comes from fields outside of medicine such as nuclear power and commercial aviation. Some quality-related terminology may not be part of the usual lexicon of pediatric cardiologists, or they may not be familiar with the specific definitions. To avoid confusion and put some of these terms in the clinical context of the heart center, the following is a brief list of definitions:

Quality: The degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge (1). Thus, quality is about outcomes: how successful are we in treating a certain type of cardiac defect? How accurately can we diagnose it?

Patient Safety: Freedom from accidental injury (2), or avoidance, prevention, and amelioration of adverse outcomes or injuries from the processes of health care (3). This is different from employee's safety only in point of view. The practices that maximize patient safety will also maximize employee safety.

Adverse Event: An injury that is caused by medical management, not the patient's disease (2). Not all adverse events are preventable. Not all untoward outcomes are the result of adverse events. An untoward outcome in the absence of medical mismanagement may not be preventable.

Medical Error: An event where a planned action is not carried out or carried out incorrectly—an "error of execution" or an event that happened because of a faulty plan—an "error of planning." (2,4) James Reason (4) further dissects the anatomy of medical errors into slips, lapses, and fumbles. A *slip* is when individuals do something they are not supposed to do, a *lapse* is when they don't do something they are supposed to do, and a *fumble* is when a normally well-executed task is simply bungled.

Swiss Cheese Phenomenon: Another concept popularized by Reason is that most significant adverse events are not the result of a single medical error. They are the result of a series of failures of the barriers (usually policies and procedures) that were intended to protect the patient. Each barrier is represented as a slice of cheese. The barriers are not perfect, and the holes in the Swiss cheese represent areas where the barrier could be breached. For an error to reach the patient and cause harm, all the holes in the various layers of Swiss cheese must line up.

QI work requires a change in the mindset for many clinician scientists. QI in health care consists of systematic, data-guided activities designed to bring about immediate positive changes. QI tools are used as deliberate actions guided by data that reflect the effects of those actions. QI is an overarching ongoing process to improve the outcomes of health

care delivery and as such is different than more traditional research that is aimed at answering a specific question over a discrete time (5). Further, most clinician scientists are trained in the traditional model of research (randomized trials with treatment groups and control groups) wherein an intervention is introduced while controlling for all or most other variables and then examining the result. Often a comparative group is monitored that did not receive the intervention. QI work, on the other hand, seeks to monitor the system in real time, introduce interventions, and monitor for how the system responds and then introduce further interventions until a desired and measurable outcome is achieved. QI does not attempt to control system variables as interventions are introduced. Understanding complex system interactions rather than controlling them distinguishes QI from intervention-based research trials.

This chapter is intended to guide the cardiology specialist through an overview of quality- and safety-related principles. We have chosen to use a clinical case scenario that caused significant harm to a patient to illustrate QI concepts and tools. The case is based upon a cardiac intensive care unit (ICU)-related medical error but could have happened in the pediatric ICU or even in a general care unit.

CASE STUDY

TJ was a 4-year-old female patient with truncus arteriosus who was admitted for replacement of an obstructive right ventricle to pulmonary artery conduit.

The surgery was routine, but postoperatively the chest tube output was high and bloody. Her hemoglobin level dropped from 10.5 to 7.0 g/dL over the first 4 hours postoperatively. Tachycardia developed, and in response, the attending physician ordered 1 unit of packed red blood cells and fresh frozen plasma to be given as soon as possible for this blood type O negative patient.

Meanwhile, a new patient arrived from another hospital and was being placed on extracorporeal membrane oxygenation (ECMO). The ECMO team had ordered 2 units of packed red blood cells (A positive) as well as fresh frozen plasma and platelets.

TJ's chest bleeding was not decreasing, so preparations were made to take her back to the operating room to explore for a bleeding site. Her blood pressure was beginning to drop, and the critical care physician asked for the blood to be delivered to the ICU "stat." Shortly thereafter, the blood bank technician appeared in the ICU with blood in hand for the ECMO patient, but was unfamiliar with the physical layout of the unit. TJ's nurse saw the blood bank technician looking in the door to ask for directions, and assumed that blood was what had just been ordered for TJ. The nurse signaled the technician into the room and received the blood. TJ's blood pressure was dropping rapidly, so the decision had been made

to not take the patient to the OR, but to explore her chest in the pediatric intensive care unit (PICU). As the surgeon was donning gown and gloves, he indicated an urgency to get the blood running quickly, so the blood was hung and a rapid infusion was started.

Within 5 minutes, as the chest was being prepped, TJ's urine turned red. She had worsening hypotension and increased bleeding. An acute hemolytic transfusion reaction was confirmed when the donor blood was identified as the A positive blood intended for the ECMO patient down the hall. The transfusion was immediately discontinued. Steroids and mannitol were given while the exploration was under way. The transfusion was reinstituted when the correct O negative blood originally intended for TJ arrived. A source of active bleeding was found and surgically corrected, but diffuse oozing continued. Serum potassium rose over the next 2 hours to 7.5 mEq/L along with the development of anuria. Despite an infusion of insulin and glucose, mannitol, intravenous hydration, Kayexalate enemas, and intravenous calcium, cardiac arrest ensued from which the patient could not be resuscitated.

A serious safety event was declared, and a root cause analysis (RCA) was carried out.

Root Cause Analysis—A Road to Resolution: What Happened and Why

TJ's Case: The wrong blood was given to TJ. A subsequent cause analysis of the event revealed: (a) the perceived urgency of blood administration was used by the nurse as a reason to "skip" the double check that should occur prior to all blood product administration (an "individual failure"); and (b) the hospital and blood bank did not have a clear and well-known double check policy (with consequences for policy violation) prior to all medication and blood product administration (a "system failure.")

RCA is a framework used in industry and recently applied to health care that is utilized retrospectively to determine system and individual causes of adverse events. In 1996, the Joint

Commission mandated that an RCA be done on all reportable sentinel events including "mismatched blood administration with transfusion reaction," yet the literature to date supporting the effectiveness of RCA is limited. In 1998, the Veteran's Administration (VA) National Center for Patient Safety (NCPS) was established. Bagian et al. (6) transformed the VA system of cause analysis by implementing a frontline staff-driven process that emphasized searching for system vulnerabilities with actionable solutions and de-emphasizing the less actionable human error root causes. Recently, Percarpio et al. (7) examined the evidence that RCA improved patient safety. From among 38 references, 11 case studies used clinical or process outcome measures to assess RCA effectiveness, described corrective actions, and outlined improved clinical outcomes subsequent to the RCA. Examples of improved outcomes included reduced mortality following various surgical procedures, reduced numbers of patient falls, and improved liver transplant graft survival. However, no pediatric studies were reported.

There are multiple templates used to complete an RCA, with all involving a description of the event with a timeline, identification of causal events, and suggested corrective actions (7,8). Causal factors are often broken into subcategories such as patient factors, caregiver factors, team factors, and technology or environmental factors (8). Asking the question, "why?" five times has been used to help identify all the contributing factors associated with an adverse event (9). The responses obtained to these "why" questions are used to help create a cause-and-effect diagram. This cause-and-effect diagram or "fishbone diagram" can also be used to help map the process and better categorize root causes. The main categories of factors contributing to the event are listed in the various "branches." Within each major branch, smaller branches may be added describing the deeper issues within each category (Fig. 77.1). Percarpio et al. also include "measures to track improvement" and "baseline with follow-up data" to the aforementioned RCA framework.

There are several limitations associated with how most RCA work is completed. Many resources are required by frontline staff and hospital leaders with limited evidence that the RCA process improves patient safety or quality. Primary limitations

Figure 77.1. Cause-and-effect (fishbone) diagram for the TJ's case.

are more related to the implementation of the RCA process and include: (a) narrow scope (limiting the findings to only the event in question rather than generalizing to other areas of the hospital system); (b) lack of reliable implementation of the identified corrective actions and follow-up to ensure the corrective actions are sustained; (c) too much focus on the individual human error (punitive culture) and less on the larger system that enabled the individual to fail; and (d) hindsight bias by the RCA team because the RCA, by definition, is conducted after the event has occurred.

In contrast to the retrospective RCA approach, the Healthcare Failure Modes and Effects Analysis (HFMEA) method utilizes a prospective approach to adverse event analysis. By anticipating where problems may occur or proactively analyzing high-risk processes before they are implemented, hospitals may use the HFMEA process to prevent adverse events, rather than reacting to an event that has already occurred. A commonly used HFMEA template was designed by the VA NCPS and involves five steps to assess a health care process: (a) identifying the topic, (b) forming of a multidisciplinary team, (c) creating a graphical description of the process, (d) performing a hazard analysis, and (e) developing actions and identifying outcome measures (10). The hazard analysis (step d) is an essential part of the HFMEA process and uses a mathematical scoring system to prioritize risk and potential errors (failure modes) in the process being evaluated. Scoring takes into account the probability of the failure actually happening as well as the consequences of the failure if it did occur. Failure modes with high scores get prioritized to develop a mitigation strategy and action plan to be followed if the failure happens. Recently, Ashley et al. (11) have questioned the reliability of the mathematical scoring systems in use today that result in very different prioritization recommendations for the failure modes. They suggest that a consensus scoring system should be developed to mitigate this possibility.

Our organization and a few other US pediatric hospitals have collaborated with Healthcare Performance Improvement, LLC, to implement a robust RCA process as part of a larger high reliability strategy to improve safety and quality outcomes. RCAs are triggered by serious harm events, near-miss harm events, or Joint Commission "sentinel events." Joint Commission sentinel events are "an unexpected occurrence involving death or serious physical or psychological injury, or the risk thereof." (12) Sentinel events are identified by the outcome without consideration for preventability or whether there was a variation from expected care practices that caused the event. In contrast, a serious harm event starts with a deviation from best practice that results in serious harm. Therefore, a serious harm event includes both the causal process and the untoward outcome.

The RCA model we are using involves a careful reconstruction of the timeline describing the sequence of actions preceding and following the harm event. The timeline description requires interviews with all staff involved in the event along with a review of pertinent policies and procedures. Inappropriate actions are identified when there is deviation from expected practice or local or national policies/guidelines. The timeline and possible inappropriate actions are discussed by an RCA team composed of individuals who are *not* involved in the harm event but are knowledgeable of the patient care processes that failed. The RCA team is led by an executive sponsor whose role is to help the RCA team when or if they reach system barriers that require executive interventions. Root causes, once identified, are discussed by the RCA team and corrective actions are codified. The root causes are categorized into system or individual failure modes. There are multiple subcategories within the larger system or individual failure groupings. This subcategorization is intended to make it easier to find common causes for adverse events, even if the

specifics of the various events are disparate. Individuals who possess the authority to implement the corrective actions are identified, and a timeline for implementation is established. An expected date of completion is recorded and follow-up by QI staff takes place to ensure that the corrective actions have been implemented and are sustained.

TJ's Case: TJ received the wrong blood. **System failures included the following:** The hospital did not have a clear, consistent method and policy for double-checking blood products. Additionally, the expectations and potential consequences of violating a double check were not clearly understood by all staff members. **Individual failures included the following:** The nurse did not perform a double check prior to blood administration to ensure that the blood was intended for her patient, although she knew the double check was necessary. The blood bank technician did not confirm delivering the blood product to the correct patient bed. **System corrective measures included the following:** Establish a hospital-wide policy regarding how blood products are ordered and delivered to the patient. Require a mandatory double check of blood products (as well as high-risk medications) by all staff members. Provide education to staff members regarding this policy as well as provide background to why it was established. **Individual corrective measures include:** Provide coaching to the nurse involved as she chose to take an unacceptable risk, but has no prior history of safety issues. Provide required education and increased supervision of this nurse and blood bank technician.

When Individuals Fail

There are several individual failures that may have contributed to the preventable harm suffered by TJ. The care provider likely realized that a double check of the blood transfusion was required. However, because the environment in the ICU was hectic and the patient was unstable and deteriorating rapidly, this important step was omitted. Health care has often promoted a "culture of blame" when individuals fail. "Who messed up?" is often the first question when patient harm occurs. Individuals are blamed for errors when hospital leadership fails to recognize the influence and impact of a "flawed" system on individual performance. How was the system designed to "help the individual fail?" The "blame culture" leads to decreased reporting of errors and further impairs the ability of leaders and frontline staff to identify and fix system-related issues. Nevertheless, it is easier to blame someone and resort to familiar solutions such as "counseling, disciplinary action, enforcing rules, or developing new rules" rather than finding the root cause of systemic problems. Reason's "Swiss Cheese Model" outlines how systems have flaws (holes in the cheese) that when lined up appropriately will make it easier for the individual failure (an error) to reach the patient and ultimately lead to a patient being harmed (Fig. 77.2) (13). Providers and patients become the victims of systems that are inadequately designed to prevent or reduce human error. Punishing the individual will not reduce the error rate. In fact, in an environment of blame, staff members are less likely to report errors or near-miss errors. James Reason has been quoted as saying, when an individual forgets (a slip), there is little value in "putting a carcass on the wall" to demonstrate that the problem is fixed (14).

Nevertheless, sometimes individuals who make mistakes leading to patient harm should be held accountable for their individual failures. A healthy safety environment is one that balances the "blame-free culture" with fairness regarding personal accountability. The term "just culture" has been used to describe this cultural balance (15,16). A "just culture" environment is not totally blame-free, but rather a culture in which the process for evaluating errors is clear, transparent, and carefully separates blame-worthy from blame-less acts. In

Figure 77.2. Chain of events passing through corresponding holes in layers of defense (Swiss Cheese Model). (Concept adapted from J Reason. *Managing the Risks of Organizational Accidents*, 1997 by Healthcare Performance Improvement, LLC © with permission.)

this case scenario, blaming the individual and removing the employee likely will not prevent a similar episode from occurring by another employee. The system must be constructed to make it easier for employees working in the high-stress ICU environment to stop and think prior to proceeding with a safety critical act (e.g., double-checking patient records prior to blood administration). Since “just culture” does not imply “blame-free,” determining culpability is essential. James Reason (17) provides an algorithm for assessing individual culpability associated with unsafe acts, which is consistent with a just culture. Through a series of questions, leaders can assess individual culpability: Were the actions and consequences intended? Is there a medical condition (e.g., substance abuse or chronic illness) involved? Did the individual knowingly violate a safe operating procedure that was readily available to and understandable by the individual? Would others in the same circumstances do the same thing? Does this person have a history of unsafe acts? Based on the answers to these questions, stages of diminishing culpability can be assigned ranging from criminal negligence to blameless error (Fig. 77.3).

The Improvement Team—Aim, Key Drivers, and Interventions Developed by the Team

Multiple methodologies have been described to fix failing systems including the Model for Improvement, Six-Sigma DMAIC, Lean Improvement, and the Seven-Step Problem-Solving model (18). These methodologies have many similarities and use many of the same tools to implement change. One of the most widely used methodologies in health care is the Model for Improvement. This method “attempts to balance the rewards from taking action with the wisdom of careful study before taking action” (18). The Model for Improvement starts with three questions (Fig. 77.4):

1. “What are we trying to accomplish?” Define your improvement project in the form of a specific aim that states what you intend to improve, by how much, by when, in what

population, and for how long. The specific aim should be concise, measurable, and achievable. This is most likely to happen when your specific aim includes SMART elements. That is, it should be Specific, Measurable, Attainable, Relevant, and Timely (see below).

2. “How will you know that a change is an improvement?” If the system that requires improvement is relatively simple, the improvement should be obvious. That may not be the case for more complex systems. Choosing the right metric(s) is critical to the success of the improvement project.
3. “What changes can we make that will result in improvement?” Ideas for improvement can come from a variety of sources such as peer-reviewed literature, a detailed analysis of internal data or identification of best practices used by other organizations or industries. Often, improvement ideas can be generated by QI teams through group process activities such as brainstorming, nominal group technique, process mapping, the development of a fishbone diagram, or the use of tally sheets.

Through an iterative Plan-Do-Study-Act (PDSA) process, improvement ideas become “tests of change” that are developed (Plan), implemented (Do), monitored (Study), and interpreted (Act). Plan: Each “test of change” is based on a prediction that improvement will occur. Each PDSA cycle tests that prediction and learning is acquired. Other factors that should be considered in determining the size of the first PDSA include: (a) the readiness of the system for change, (b) the probability the proposed system change will work, and (c) the consequences to the system if the proposed system change fails. The less ready the system, the lower the probability the change will work, and the greater the risk if the change fails, then the smaller the first PDSA should be. Do: Carry out your plan on the limited scale that you planned and see what happens. Study: Study the effect of the “test of change” on the process being changed. The data derived from each “test of change” generate new knowledge or learning and influence the next test of change. Act: After interpreting the results of the first cycle, determine next steps. It is this learning that fuels

Figure 77.3. Accountability grid—just culture. (Concept adapted from J Reason *Managing the Risks of Organizational Accidents*, 1997 by Healthcare Performance Improvement, LLC ©.)

Figure 77.4. The model for improvement. (Adapted from Berwick DM. A primer on leading the improvement of systems. *BMJ* 1996;312:619–622.)

the action that initiates the next PDSA cycle. The PDSA process is repeated incorporating the learning from the previous cycles. Because all improvement involves change, but not all change is improvement, PDSAs should usually start on a small scale with just a few patients or staff. Some improvement ideas are not successful, and must be abandoned. As the confidence in the “test of change” improves with each cycle, the size of the PDSA cycles can be “scaled up involving more staff or patients” until the new process becomes the norm.

Specific Aim and Key Driver Diagram

The aim and key driver diagram is a tool used to organize the quality team’s theories of improvement. It is intended to focus and target the work of the team. In TJ’s case, a team was charged with creating a reliable process to guarantee the use of a “double check” prior to the administration of blood products. They organized their team by developing a well-defined aim statement, key drivers, and interventions necessary to reach the stated aim.

SMART aims must be *specific*. What is the goal? What is to be achieved? Importantly, an improvement aim must be designed to improve only one thing. SMART aim statements are *measurable*. An increase or decrease in the measure will be directly associated with the desired change in the process being changed. SMART aims are *actionable*. The team empowered to improve a failed process must be able to impact the process and overcome any barriers to improve-

Figure 77.5. Key driver diagram—increase compliance with the “double check process” for blood administration.

ment. SMART aims are *realistic* in that there must be a reasonable expectation that the aim can be achieved. A realistic aim statement often requires that it be “bounded” or narrowly focused. The team may limit their improvement work to a single unit, patient care service, or a defined patient population. By doing so, the team can test changes on a small scale prior to spreading the improvement ideas to other areas or patient populations. Finally, a SMART aim must be *timely*. The improvement aim must have a target date by which it will be completed. If that date is more than 6 months from the beginning of the improvement work, interim milestones of improvement should be set. While all elements of a SMART aim are important, the two that often lack clarity are the elements of measurability and timeliness. Poorly constructed aim statements speak of improving failed processes, but do not define how much improvement is expected and by when the improvement is expected. During his 2004 IHI Key Note address, Don Berwick, former President and CEO of the Institute for Healthcare Improvement stated this concept well, “Some is not a number, soon is not a time.”

TJ’s Case: A team was codified to examine and put in place reliable processes to prevent a similar occurrence from happening. Specifically, the process had to ensure that “double checks” were consistently done prior to any blood product administration. The team developed the following SMART aim statement (Fig. 77.5): To improve the compliance of the “double check” process for blood administration in the ICU from 50% to 95% within the next 90 days. This aim statement presumes that the process for a correct “double check” is already known and that a baseline compliance rate of 50% had been established through a preliminary audit of the process in the ICU.

Key drivers are those factors that the team believes will impact the failed process and bring about improvement. The key drivers can often be identified from the RCA process, or a “cause-and-effect” or “fishbone” diagram. Sometimes, a key driver can be found in the mapping of the failed process. In the case of the failed “double check” process for blood administration, key drivers might be (a) the “double check” policy, (b) employee orientation/education, (c) blood bank policies and procedures, and (d) staffing in the PICU.

Each key driver is associated with “interventions” that, if implemented, should influence the key driver in order to drive toward achieving the specific aim. The interventions are the “tests of change” that form the basis of PDSA cycles. For example in TJ’s case, hospital employees may not interpret the “double check” policy the same way. An intervention for this key driver could be an informal survey of PICU staff to determine ambiguities or potential misunderstandings in the “double check” policy. If ambiguities are discovered, a second intervention would include reviewing the policy with a multidisciplinary team to broaden input and reduce ambiguities. A third intervention might include a test by ICU staff to make sure the policy is clear, can be implemented without problems, and compliance with the policy can be measured. Once this is done, a fourth intervention is to implement the policy throughout the organization. A sample of aim and key driver diagram for the failed “double check” process for blood administration in the PICU is shown in Figure 77.5.

Teams

A successful QI project begins with establishing a team whose members understand their roles, responsibilities, and expectations (19). An ideal improvement team should include individuals who “work in, own, supply, have knowledge of, or receive benefits from the work process” to be improved. Team members share the responsibility of the improvement work both in and outside the team meetings and should represent a cross-section of the organization that utilizes the process to be improved. Some team members will have very specific roles.

Every team must have a leader. In general, the team leader is the person who owns the process. The leader coordinates and directs the improvement work as the team studies the process and develops “tests of change” that might lead to improvement. The leader is not a passive team member. The team leader should have the authority to effect change or be empowered to break down barriers that the team may encounter. The leader contributes ideas, participates in data interpretation, and facilitates team decision making.

An improvement team needs a recorder. This role need not be the same person for every improvement team meeting, but the team leader should clearly identify who should serve as the recorder for each meeting. The recorder's responsibilities include logging significant content in such a way that all team members can see the information. This can be done with a flip-chart or from typed notes recorded from a laptop and projected. Visual display of team discussions enhances team meeting efficiency. A QI facilitator may be a team consultant bringing the knowledge of QI tools and techniques to the content experts about the process being discussed. The facilitator may provide "just-in-time" training to teach the use of a QI tool or technique that is required as part of the improvement process.

Finally, a QI team must have a sponsor. The sponsor is the executive leader who is the champion for the improvement project. While not an active member of the improvement team, the sponsor has a critical role. The sponsor makes sure that the right people are on the team. The sponsor resolves conflicts and any barriers to success. The sponsor secures resources for the team to do its work.

For projects that cross many boundaries within an organization or hospital, a team charter may be a useful tool to codify the scope and authority of the improvement team. The charter should outline the project's focus and reasons for the effort. It should define the expected outcomes and measures that will be used to define success or failure. The charter should address the project scope (including boundary limits) and define the sponsor, team leader, facilitator and team members, the project start date, and end date.

TJ's Case: Recommendations for immediate change to the process were made to correct individual and system-related failure within hours of the event. The RCA committee also recommended that a QI team be established. The QI team was to review the process in greater detail, identify additional safety measures, monitor the performance of the process over time, and report quarterly to the hospital's Quality Improvement and Safety Committee. As the process of blood product delivery to the various ICUs was different from that of the medical-surgical units, the recommendation directed the committee to limit (bound) their scope to the ICUs.

The medical director for QI was assigned the responsibility for establishing the QI team and serving as its sponsor. The chief of the blood bank was asked to lead the team, and the

QI coordinator for the intensive care services was asked to facilitate the team. Team representatives included the medical and nursing representatives for the neonatal, pediatric, cardiac, surgical, and bone marrow transplant units. At the first meeting, the QI team developed its charter and determined its specific aim. A flowchart for the current process of blood product delivery to the ICUs was developed and failure points were determined. A historical review of serious safety events related to blood product administration was conducted, and a Pareto chart of different error types was developed. A Pareto chart displays types of errors by frequency so that attention can be put on the relatively few types of errors that cause the majority of events (e.g., Figs. 77.7 and 77.8). A cause-and-effect diagram was constructed and the "whys" for failures were determined. From this analysis, four key drivers were developed. These were (a) failure of the hospital's "double check" process, (b) inadequate training and orientation of new employees, (c) confusion regarding hospital policies and procedures, and (d) inadequate staffing of the cardiac ICU during times of high census (e.g., Fig. 77.5).

In subsequent meetings, the QI team developed interventions (PDSAs), which they thought would impact the key drivers such that the process would be improved. One of the interventions tested was the use of a checklist when blood products arrive in the ICUs. The cardiac ICU team representatives were asked to trial a checklist and report back to the QI team regarding the checklist effectiveness at the next weekly QI team meeting (Fig. 77.6).

Bundles and Checklists

In 2005, Resar et al. (20) described a novel approach to QI in which three to five evidence-based best practices are "bundled" together and implemented as "one" in order to achieve a desired improvement outcome. "Bundles" afford health care providers the opportunity to deliver care more reliably and safely to patients undergoing treatments that have inherent risks, such as assisted ventilation and central line placement and management (21). When "bundles" are used reliably, outcomes improve (22–24).

Checklists can be used to remind the health care team of steps in a clinical practice process. The checklist can also be

Figure 77.6. Sample checklist trialed as PDSA by the ICU team.

Checklist for Blood Product Delivery to an ICU	
PDSA #1: Handoff of Blood Products from Blood Bank Technician to Certified ICU Clinician will utilize three-way communication	
<input type="checkbox"/>	Blood Bank Technician (<i>Initials</i>) delivers blood product to ICU
<input type="checkbox"/>	Blood technician reads product identification information to certified clinician (<i>Initials</i>): patient name, medical record number, blood product identification number, blood type
<input type="checkbox"/>	Certified clinician confirms each product identification element matches the blood product order form by immediate read back of each element
<input type="checkbox"/>	Blood Bank Technician acknowledges that the information stated by the certified clinician is correct by stating "Check".
<input type="checkbox"/>	When all identifying elements have been stated, read-back, and acknowledged correctly, then Blood Bank Technician will hand the blood product to the certified clinician

used to measure compliance with each step in the process. Checklists may represent best practices or may be “good ideas” that seem to be appropriate steps to follow in clinical care processes. Usually multiple individuals are responsible for completing different elements of the checklist, but no one person is accountable for completion of all the elements on the checklist. The use of a surgical safety checklist in the operating room time-out process prior to the beginning of an operation has been associated with significant improvement in surgical outcomes (25,26). Similarly, the daily goals sheet is a checklist used in many ICUs to remind the clinical team to cover all essential clinical care related items during daily rounds (27,28).

Data Drive Change—Don’t Let Data Paralyze the Team

TJ’s Case: The wrong blood was given to TJ. A Pareto chart analysis of medication errors at the hospital revealed that administration errors were the most common (Fig. 77.7) followed by prescribing and then dispensing errors. Within administration errors, the most common errors were failure to complete a “double check” prior to medication administration. This analysis, using Pareto’s methodology, suggests a hospital-wide problem that is most commonly due to errors associated with medication administration. A focused corrective effort, across the entire hospital, addressing reliable medication administration (including blood administration), may yield valuable results more quickly than simultaneously targeting all aspects of medication delivery.

When broken down into its component steps, the process of blood administration is complicated and without an organizing framework, it may be difficult to identify the most important steps that need intervention(s). A Pareto chart using the *Pareto principle*, or 80–20 rule can be used to focus the team’s work. This principle is based on the work of Vilfredo Pareto and states that approximately 80% of problems are due to 20% of the reasons for them (30). Identification of the most

common flaws (top 20%) in the blood administration system can be accomplished by convening frontline staff involved in blood administration and developing a process map for blood administration. They can begin by asking, “where do the problems occur?” The answers can be recorded by using a simple tally sheet to vote for the steps in the process that are most problematic. From these data, a histogram can be constructed, sometimes referred to as a “Pareto chart.” Figure 77.8 is an example of a second Pareto chart depicting feedback from frontline clinicians regarding problematic components of the process of blood product administration in the cardiac ICU. Improvement steps, designed as PDSA cycles of change, can then focus the QI efforts to those areas most likely to improve the process. For example, in Figure 77.8, clinicians identified availability of a “second check RN” to cross-check blood products as an essential and often problematic step. This information can be utilized by the improvement team to plan the first PDSA cycle of change. Similarly, fishbone diagrams, frequency distribution plots, or scatter plots can be utilized to identify and stratify steps in any process that are likely to result in improvement. (For a detailed discussion of data analysis tools, see reference (31)).

An aim (outcome) in QI work must be measurable, and data are used to quantify the results of such work. QI teams can leverage data to identify components of a process or system that have significant variation requiring targeted interventions. This can contribute to the design of tests of change. Finally, data can be used to measure compliance with interventions intended to sustain change. Data are essential to effect change, but the acquisition and interpretation of data must enhance the process of change not paralyze it. This section outlines the use of data to facilitate change.

A comprehensive discussion of statistical process control and Shewhart control charts is beyond the scope of this chapter; however, the brief summary that follows introduces the reader to important concepts in data interpretation that are

Figure 77.7. Pareto chart—distribution of adverse drug events by phases of medication use—clinical severity D-I; Jan-Dec 2010.

Figure 77.8. Blood product administration—histogram of improvement opportunities.

useful to direct QI changes (18,32). There is always variation within systems. Data may vary minute to minute, week to week, or month to month. Common cause variation (chance cause) is variation that is inherent within a system and affects all those working in the system and all outcomes from the system. An example is the variation in heart rate (± 5 BPM) around a mean normal rate of 100 BPM. Special cause variation (assignable cause) is not inherent to the system and arises when special or unique circumstances arise that perturb the system. A child, for example, develops fever and the heart rate can increase dramatically to 170 or 180 BPM. This special cause increase in heart rate deserves investigation to ascertain what perturbed the system to generate such an outlier in heart rate. Systems in control (common cause variation) do not need interventions if the data are in the goal range. Failure to recognize common cause variation as normal and acceptable can lead to wasted resources and attempts to tamper with a stable process delivering acceptable results. In fact, "tampering" with such in control systems may create unintended consequences that push the system out of control. In contrast, systems with special cause variation need interventions (e.g., PDSA targeted at the special cause) to investigate and eliminate the special cause. In its most simple form, special cause data points are 3-sigma (standard deviations) above or below the center line (mean) of normally distributed data (Fig. 77.9). The special cause data point depicted in Figure 77.9 might be the heart rate of 180 as noted in the case above. The fundamental value of depicting data in the control chart format is to identify systems that require additional interventions (e.g., a fever evaluation) or that have improved or worsened as a result of interventions. Process control charts are said to be the "voice of the process" and are powerful tools to identify significant change in response to either a test or some unknown variable that has been introduced into a previously stable process (33).

There are many types of statistical process control charts. The type of data that is being analyzed will determine the best control chart to use to display the variation in a manner that is helpful to QI work. Data may be continuous (variable quantitative measurements) or attributed (counts or classification of qualitative data, e.g., number of errors or pass/fail items). Figure 77.10 outlines the type of control chart that should be used depending upon the type of data. A more in-depth discussion of control charts and their interpretation can be found in *The Improvement Guide* (18).

TJ's Case: Data were used to focus the efforts of the improvement team's work. Specifically, the RCA team constructed a process map for the ordering, delivering, and verification that the correct blood is administered to the correct patient and to examine which parts of the process required change. The team also developed a blood product administration checklist that was to be completed prior to administering blood products in the cardiac ICU. The team wanted to confirm that the checklist was being consistently used. They gathered data by analyzing information from the completed blood administration checklist (Fig. 77.6). A control chart was used to monitor progress in the completion of all elements of the checklist (Fig. 77.11). If the "test of change" is real improvement, then further observation over time will show that the variability of the system has been reset and only common cause variability will be exhibited going forward. At this point, the system is once again stable and predictable with high compliance in the use of the checklist.

Statistical process control data analysis is a powerful tool to maximize the efficiency and effectiveness of process improvement teams. These kinds of charts may, however, allow the teams working on improvement to forget that the elimination of all errors that cause harm is the goal in health care, however difficult that might be to achieve. In our organization, the drive to zero is measured by "numbers of patients harmed" and even if a system is "in control," the goal remains zero defects

Figure 77.9. Control chart with special cause variation.

Figure 77.10. How to choose a control chart. (Adapted from Langley GJ, Moen RD, Nolan KM, et al., eds. *The improvement guide: a practical approach to enhancing organizational performance*. 2nd ed. San Francisco, CA: Jossey-Bass, 2009.)

Figure 77.11. Annotated p-chart measuring cardiac ICU compliance with components of the 10-point pre-blood administration checklist. The system is stable through patient number 30, with average checklist compliance at 76%. A PDSA cycle based on feedback from frontline staff resulted in a shift to 92% compliance. The new system is also stable but delivers improved performance.

(errors) (34). For example, a process control chart depicting the incidence of adverse transfusion reactions per 1,000 units transfused could be created and used as the metric to monitor blood administration errors. This graph is likely to show that transfusion reactions are uncommon and represent common cause variation, and while regrettable, the rate of transfusion reactions does not achieve special cause variation. It is our view, however, that an approach to data analysis that utilizes rates of harm event and the total number of harm events is the best combination to achieve a motivated workforce to work to achieve zero preventable harm.

High Reliability—Do What You Say and Say What You Mean

Systems Thinking

“Every system is perfectly designed to achieve the results it gets.” This statement, attributed to Paul Batalden, MD of Dartmouth School of Medicine (35), is an often quoted QI axiom. Stated another way, Albert Einstein said, “continuing to do the same thing over and over again and expecting a different result is insanity” (36). Thus, if one expects to achieve different results, the system must be changed.

An understanding of how a hospital or health care network is an integrated system with multiple interrelated and interdependent parts is an essential concept associated with QI. James Reason (17) defined a system as a set of interdependent elements interacting to achieve a common aim. Those

interdependent elements may interact to achieve a desirable aim or an undesirable one. As improvement teams or individual practitioners work to achieve the best possible outcomes, understanding the interdependency of the various processes that comprise the delivery of health care is critical. For example, if “first OR case start times” are predictably delayed and the entire OR schedule is disrupted, only a process redesign can change the outcomes. In the case of TJ, if there is a problem with the process of blood administration and the desired outcome is to make that delivery process a highly reliable error-free process, then only a study of all the interdependent parts (the system) will lead to optimal system performance and the desired outcome.

Human Factors That Contribute to Error

Human factors science is a multidisciplinary field that combines the expertise of psychologists, engineers, industrial designers, statisticians, and others. It concerns the understanding of human capability and the application and integration of this knowledge to system design. A human factor is a physical or cognitive characteristic that influences how people interact with systems. For example, in 2006, the FDA issued a recall of an infusion pump with a sensitive keypad for setting infusion rates. The sensitive pad sometimes produced a “key bounce” that resulted in a number to be entered twice when it was only intended to be entered once. Hurried nurses who failed to catch the error through pump programming verification were prone to make 10-fold errors in the infusion rates. Human factors such as fatigue, stress, external distractions, and personal issues are likely to blame (though the device itself may also

be poorly designed). The interaction between technology and humans is of particular importance in the high-tech hospital environment, particularly the ICU. At various safety critical moments (e.g., high-tech device interfaces with human being), it is important to recognize when human factors may impair performance. This has been called situational awareness. Situational awareness is “the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of the status in the near future” (37). A lack of situational awareness is one of the individual failure modes, and is a common root cause of errors during safety critical functions such as blood product administration. Endsley (37) further emphasizes the importance of distinguishing situational awareness that is a “state of knowledge” from situational assessment that is the process by which that “state of knowledge” is attained and operationalized. Certainly, health care workers cannot avoid performing safety critical acts, and those same workers cannot avoid the burden of human factors. However, it is possible to modify human behaviors to recognize when human factors are at play and practice simple safety practices to aid performance. One such practice is the *STAR* technique that can be used prior to performing any safety critical function. For example, before administering an intravenous medication, the health care worker can Stop for a moment. Think about the critical act about to be performed (right patient, right dose, etc.) prior to performing the Act. Then, immediately Review what was just done. Were all elements performed correctly? The *STAR* technique is a useful tool to enhance situational assessment that facilitates better situational awareness. If the *STAR* technique had been used by the ICU nurse prior to starting TJ’s blood transfusion, it is quite possible that the error would have been prevented.

Creating High Reliability Organizations

Unexpected events are common, and high reliability organizations (HROs) are structured to anticipate and react to the unexpected. HROs recognize lapses early, learn why they occurred, and respond to mitigate the minor lapses before they result in catastrophic failure. HROs are always mindful of what is happening within and to their systems. In a way, HROs engage in a form of “institutional situation awareness.” Weick and Sutcliffe (38) have described the characteristics of HROs. Those characteristics are now being explored and more fully integrated into the health care environment. HRO characteristics include the following:

1. Preoccupation with failure, to track small lapses as if they were symptoms of a system about to fail catastrophically
2. Resisting oversimplification, seeing a more complete and nuanced picture of complex systems that are riddled with the unstable, unknowable, and unpredictable.
3. Remaining sensitive to operations and to relationships; realizing that frontline staff have knowledge that leaders lack, and staff willingness to report that knowledge is key to identifying the small failures before they become catastrophic.
4. Maintaining capabilities for resilience such that, while not error-free, HROs are not disabled by their errors. They keep errors small and utilize workarounds that allow the system to keep functioning.
5. Deferring to expertise and taking advantage of changing locations of expertise. HROs are culturally diverse, lack rigid hierarchies, and drive decision-making down to the frontline staff. Authority migrates to the person with the most expertise, not necessarily the most experience.

HROs learn both from successes and failures. It is often the failures that derive the greatest learning. Weick and Sutcliffe (38) further state that the two perceived enemies of HROs are

“complacency and hubris.” Health care organizations often have too much of both.

If the ICU in which TJ was hospitalized was part of an HRO, a different outcome would be expected. While staffing issues are always a factor in busy, high-acuity ICUs, an ICU in an HRO hospital would have had processes in place to address the likelihood that multiple, critically ill patients might require blood administration at the same time. A standardized hand-off of the blood product from the blood delivering personnel to the ICU staff would exist. A clearly understood process for “double-checking” the blood received against the order placed and TJ’s identification band would have been used. A redundant system of “double checking” using bar coded information that linked the blood unit “bag tag,” the order for blood product, and TJ’s identification band would exist. Finally, immediately prior to initiating the blood administration, TJ’s nurse would have stopped and thought about the safety critical nature of blood administration (*STAR*) prior to connecting the blood. The nurse would have confirmed that the right unit of blood was about to be administered to TJ. Each of these steps would have required no more than a few additional seconds of staff time. In an ICU in an HRO hospital, the entire episode would have occurred as part of routine patient care and no one would think to do otherwise.

Culture—an Essential Ingredient

Although not a tightly defined scientific concept, the role of culture is widely recognized as an important part of the fabric of any health care organization. Hospital mission and vision statements are rigorously crafted and widely recited by employees throughout the organization; however, the culture of an organization is not so easily defined. The way people behave at 3:00AM when nobody else is watching is what really defines an organization’s culture. In the middle of the night, does the nurse always check two patient identifiers when giving medications to a patient with whom she is very familiar?

TJ’s Case: TJ was rapidly decompensating and TJ’s physician and nurse were rushed, worried, and in a hurry to get the blood product administered quickly. Because of those distractions, they skipped an essential double check to ensure this was the correct blood for the correct patient. The consequences of by-passing this step is clear. It is likely that, when not rushed, this standard step is virtually always done by these two clinicians. When rushed and distracted, individuals may forget essential steps unless those steps are “habit” or a forcing step is in place that cannot be by-passed. If these two individuals are the only ICU staff who would make this mistake in this setting, then these are individual failures. However, if in this ICU, clinicians often use shortcuts when stressed, then the ICU has a culture of noncompliance, which if unaddressed will lead to recurrent errors, in particular during safety critical processes.

A safety culture does not occur spontaneously. Zohar (39) summarized organizational characteristics of companies with low accident rates. The most important factors included: (a) successful safety program with strong leadership commitment, (b) safety training for all the workforce, (c) a senior official as a safety officer, and (c) safety promoted through guidance and reinforcement instead of admonition. Health care professionals have begun to recognize the importance of having a strong safety culture as a method to improve quality and safety (40,41); however, controversy remains regarding how to measure and quantify the benefits. Measuring improvement in safety culture is a process measure that may reflect improved actual safety; however, the more important metric would be to correlate improved safety climate with improved clinical outcomes.

Tools that measure safety and teamwork culture within a health care system are increasingly accepted as valid metrics that reflect the climate of opinion among various professional groups. While a variety of survey tools are available, two tools commonly in use are the Safety Attitudes Questionnaire (SAQ) and the Agency for Healthcare Research and Quality (AHRQ) Hospital Survey on Patient Safety Culture. The SAQ is a proprietary survey currently administered by Pascal Metrics (42). Several versions of the SAQ exist and focus upon ambulatory, inpatient, or emergency departments. The survey examines multiple domains including teamwork, safety, job satisfaction, stress recognition, working conditions, and perceptions of unit and hospital management. Studies have demonstrated a link between the SAQ safety and teamwork climate and clinical outcomes. In a large cohort of ICUs, high scores (e.g., >80% on a 100% scale) were associated with lower rates of complications such as bloodstream infections and scores below 60% were associated with higher infection rates (43). Recent papers describe the use of SAQ survey results to both assess and improve the safety environment in various health care settings (44–46). Using the results of the SAQ, Sexton et al. (47) documented the ability of a comprehensive unit-based patient safety program to change the teamwork and safety climates in ICUs across an entire state. The SAQ results can also demonstrate disparate perceptions about safety and teamwork climates between different professional groups within the same ICU (48,49). The other widely used cultural survey is the AHRQ Hospital Survey on Patient Safety Culture. The survey was first released for public use in 2004 and is available for use online (50), free of charge. The survey measures 12 areas or composites of patient safety culture including communications openness, feedback and communication about error, handoffs and transitions, teamwork across units, and others. Over 900 hospitals currently use this survey and the aggregate results are available for benchmarking between hospitals (51). As with the SAQ, the AHRQ scores can be broken down by specific unit and/or by caregiver type. Early studies attempting to link the AHRQ Hospital Survey with clinical outcomes showed mixed results (52–56). Some of the discrepancies among the studies may be related to the use of the AHRQ Patient Safety Indicators (AHRQ PSI) as the outcome measure. The database from which the AHRQ PSIs are generated is the Healthcare Cost and Utilization Project (HCUP). HCUP catalogs inpatient discharge data from 44 participating states. Multiple data elements are extracted, and severity adjustment is done using APR-DRGs and co-morbidity groupings. Each PSI is a rate, with the numerator being the number of cases with an outcome of interest (e.g., Central venous catheter-related bloodstream infection (CLABSI)) and the denominator is the population at risk (e.g., number of patients with a central venous line during that time period). Currently, 18 PSIs include CLABSI, death in low mortality DRGs, postoperative sepsis, pressure ulcers, and 14 other indicators. The AHRQ PSI is an administrative database and published studies outline its limitations including (a) insufficient clinical detail and risk adjustment and (b) its dependency upon the accuracy of documentation and coding and caution against using it as a definitive outcome metric (57–59). However, recently, Mardon et al. (60) examined data from 179 hospitals and using refined and updated PSIs found that a positive patient safety culture was associated with fewer adverse events in hospitals. Indeed, the preponderance of evidence suggests that improved safety culture is associated with less patient harm, no matter what survey tool is used.

Hospitals focused on transformational change to achieve improved safety-related outcomes will be focused not only on cultural change but also will have active QI teams focused on strategic projects such as reducing bloodstream infections, pressure ulcers, and adverse drug events (e.g., blood administration errors); both are essential. The health care drive to

eliminate harm and improve quality and safety will occur only in hospitals with strong safety and teamwork climates. Such hospitals will have environments where (a) an error or a near-miss error is viewed as opportunity to improve, and leadership takes the opportunity to find the commensurate system solutions; (b) all personnel feel responsible for not only their work but for that of their partner; and (c) all team members are comfortable speaking up when a team member (even a senior one) is getting ready to make an error. These characteristics can only enhance the likelihood of success of the focused teams mentioned previously. Future research using cultural assessment surveys may help distinguish the relative importance of each.

Design, Execution, and Appraisal of Clinical Trials

Brian W. McCrindle

WHAT IS EVIDENCE-BASED MEDICINE AND WHY ARE CLINICAL TRIALS SO RELEVANT TO THAT PRACTICE?

Definition and Practice of Evidence-based Medicine

The practice of evidence-based medicine occurs when clinical decision making involves the incorporation of the best available research evidence together with the clinician's expertise and consideration of local or individual circumstances and the patient's preferences regarding therapies and outcomes. An additional step involves tracking, appraisal, and updating of the process. As a result, the practice is not based solely on research evidence, and should not be viewed as a directive or "cook book" approach. The sequence of steps in the practice of evidence-based clinical decision making is outlined in Table 78.1.

Both Absence and Proliferation of Evidence

The important necessary first step includes a search for applicable research evidence to inform the clinical question at hand and a critical appraisal of that evidence and subsequent synthesis. Given the exponential expansion of both available evidence (i.e., the medical literature and proliferation of journals) and the ease of means to access it (i.e., searchable databases like PubMed, proliferation of open access journals), clinicians in search of answers are often faced with having to sift through hundreds or thousands of individual articles. The task often seems very daunting, and so one may resort to expert opinion or review articles (often just another form of expert opinion) or to the claims of industry. This is actually largely what many patients are doing, making their own decisions on the basis of what they are exposed to in the media or what they are told by other lay people. The popular "news" media are fraught with errors in both reporting the facts and their interpretation, are prone to sensationalism, and in the obligation to provide balanced viewpoints often resort to inclusion of dissenting unsupported opinions from the fringes of reason. An unregulated claim extolling the curative wonders of an alternative or complementary health product of unproven effectiveness or safety may carry more weight than the best evidence-based recommendation from their health care provider. Together with rising health care costs and stories regarding conflicts of interest and sometimes conflicting study results, many patients have become suspicious of the health care system and abandon therapies that are of proven benefit based on best evidence, sometimes to the detriment of their own health or that of others.

Evidence and Clinical Trials

In order to provide the best possible care to their patients and to expertly and convincingly counsel them about that

care, clinicians need to be expert users and appraisers of research evidence. One needs to be able to efficiently sift through the evidence and then be able to appraise the quality of that evidence before deciding how much weight to give it in terms of clinical decision making. One is looking to find evidence that is applicable to the clinical scenario and answerable question at hand, but of sufficient quality such that one can be confident that the findings are valid and reliable or as close to the truth as one can get. Clinical trials, by the nature of their design, execution, and systematic approach to appraisal, provide the greatest potential for freedom from biases that result in deviations from the truth and, thus, represent or contribute to the highest levels of evidence. This is why clinical trials have a greater impact within systems for developing and reporting clinical practice guidelines or recommendations. Clinical trials are assigned the highest grades in terms of quality of evidence and have the greatest influence in informing the strength of recommendations, as noted in Table 78.2 (1).

HOW DO CLINICAL TRIALS ACHIEVE A HIGH GRADE OF EVIDENCE?

Well-designed and well-executed randomized clinical trials achieve a high grade of evidence for several reasons, as noted in Table 78.3.

Causality

Clinical trials provide the best evidence that any differences in the comparison of outcomes being assessed are a direct result of differences in the interventions being compared (or comparison to nonintervention or standard of care). Clinical trials provide strong evidence for defining causality and can determine the efficacy (how well it works in a research or controlled setting), effectiveness (how well it works in clinical practice), and safety of an intervention. There are several criteria for defining causality, as noted in Table 78.4. Many of these criteria are explicitly satisfied by clinical trials, and hence clinical trials provide the best evidence that an intervention either directly or indirectly (through reduction or elimination of intermediate causal factors) is the cause of observed differences in outcomes. The design and execution of clinical trials attempt to minimize confounding factors that may influence the outcomes of interest, with the observed effects then being confidently attributable to the interventions being compared. This is achieved by random allocation of study subjects, blinding of study assignment as far as possible, standardization of interventions and tracking of any cointerventions or crossovers, continuous accounting for all study subjects, and standardization of all assessments and interpretations of outcomes.

TABLE 78.1 Steps in the Practice of Evidence-Based Clinical Decision Making

1. Begin the process with a clinical scenario of immediate relevance, and specify the need for information as a well-thought-out and answerable question.
2. Obtain the best available research evidence, usually by executing an informed and efficient search strategy of the published literature.
3. Filter the results of the search by critically appraising the most relevant articles through assessment of methods and results in terms of their validity, the magnitude, and reliability of the reported effect, and their applicability and relevance to the clinical scenario at hand.
4. In addition to the appraised evidence, take into account the unique aspects of the clinical scenario in terms of the individual patient's pathophysiology, social and cultural milieu, and preferences and values.
5. Take into account your own, your colleagues', and your settings' particular experiences and resources, that is, those aspects that make up "clinical expertise."
6. From this integration and synthesis of the appraised evidence, together with the unique aspects of the clinical scenario, make the best-informed clinical decision.
7. Record, track, and update the results of the preceding process. Assess the process itself, and strive for greater efficiency and benefit when applying it to future clinical scenarios.

Bias can be further detected and minimized during the data analysis, with statistical adjustment for any unbalances in potentially confounding factors.

Randomization

The process of randomization, or random assignment of subjects to the study interventions, is a key feature of clinical trials that minimizes bias. In order for the intervention groups to be compared fairly, they must be as similar as possible regarding all characteristics and management other than the intervention to which they were assigned. In clinical practice, patients do not receive interventions at random, but usually variably based on three aspects (best research evidence, clinical expertise, patient preferences) defining evidence-based decision making. When examining the data derived from such clinical practice in a case-series review, those patients who receive one intervention versus another will likely differ regarding some characteristics that will influence the outcomes, rendering the direct comparison of outcomes unfair due to selection bias. This differential influence on outcome can be directly causal, or may have a mediating relation between the intervention and outcome, such as confounding or interaction. Random assignment of subjects helps to minimize bias from confounding by producing groups of subjects whereby baseline characteristics are similarly randomly present between groups, not only those that were measured, but also those that were not measured. Any subsequent differences between groups after random assignment should be due to chance or random error. The degree to which this achieves equivalency of the groups depends on how many subjects are being randomized, with the larger the number of subjects randomized, the smaller the likelihood that a random unbalance will be present. The success of random assignment can be tested at the end of recruitment by comparing measured baseline characteristics between groups and identifying potentially influential differences.

Prospective and Concurrent Data Collection

All clinical trials are prospective by design, whereby the main exposure, the intervention, is applied and then the subjects are

followed forward in time with assessments for the outcomes. Also, all clinical trials rely on data collection that occurs in the present or concurrent data collection as the subjects progress through the study period. This prospective and concurrent data collection allows a higher quality of data to be acquired, versus the use of secondary data such as the clinical record that characterizes the majority of observational studies. Standard definitions and measurement procedures can be applied. Central measurement and interpretation can occur in core laboratories. For more subjective measurements or outcomes, expert and independent adjudication panels can be used. Blinding is important, whereby the subjects, the study personnel and investigators, and those analyzing the data have no knowledge of the randomized assignment of the subject and which intervention was received. Blinding minimizes biases from confounding due to cointerventions. Cointerventions might occur in the application of the intervention, implementation of the protocol, application and interpretation of the measurements, and the attribution of causal relationships to adverse events. Well-meaning study personnel and investigators may provide different subjective interpretations of assessments if they know the intervention the subject was assigned. Subjects have been known to differentially report adverse events while on inert placebo if they believed that they were receiving the active study drug. Thus, clinical trials, through concurrent data collection and blinding, allow a high degree of quality control over the data collection and further opportunities to minimize random and systematic errors.

Appraisal and Regulation

The methodology of clinical trials is fairly prescribed and regimented; errors in the design, execution, or analysis are often readily detectable. If the methods and results are described in sufficient detail, the appraisal of the validity, reliability, quality, and applicability of the findings is possible. Appraisal can inform assignment of a quality and strength grade to the evidence provided by a clinical trial. Standardized reporting of clinical trials has been adopted and required by most prominent scientific journals, which facilitate appraisal. The CONSORT (Consolidated Standards of Reporting Trials; www.consort-statement.org) Statement to

TABLE 78.2 System for Grading the Quality of Evidence and the Strength of Recommendations**EVIDENCE QUALITY FOR GRADES OF EVIDENCE:**

Grade	Evidence
A	Well-designed randomized, controlled trials or diagnostic studies performed on a population similar to the guideline's target population
B	Randomized, controlled trials or diagnostic studies with minor limitations; genetic natural history studies; overwhelmingly consistent evidence from observational studies
C	Observational studies (case-control and cohort design)
D	Expert opinion, case reports, or reasoning from first principles (bench research or animal studies)

GUIDELINE DEFINITIONS FOR EVIDENCE-BASED STATEMENTS:

Statement Type	Definition	Implication
Strong recommendation	The reporter(s) believe that the benefits of the recommended approach clearly exceed the harms and that the quality of the supporting evidence is excellent (grade A or B). In some clearly defined circumstances, strong recommendations may be made on the basis of lesser evidence when high-quality evidence is impossible to obtain and the anticipated benefits clearly outweigh the harms.	Clinicians should follow a strong recommendation unless a clear and compelling rationale for an alternative approach is present.
Recommendation	The reporter(s) feel that the benefits exceed the harms but the quality of the evidence is not as strong (grade B or C). In some clearly defined circumstances, strong recommendations may be made on the basis of lesser evidence when high-quality evidence is impossible to obtain and the anticipated benefits clearly outweigh the harms.	Clinicians should generally follow a recommendation but remain alert to new information and sensitive to patient preferences.
Option	Either the quality of the evidence that exists is suspect (grade D) or well-performed studies (grade A, B or C) show little clear advantage to one approach versus another.	Clinicians should be flexible in their decision making regarding appropriate practice, although they may set boundaries on alternatives; patient preference should have a substantial influencing role.
No recommendation	There is both a lack of pertinent evidence (grade D) and an unclear balance between benefits and harms.	Clinicians should feel little constraint in their decision making and be alert to new published evidence that clarifies the balance of benefit versus harm; patient preference should have a substantial influencing role.

TABLE 78.3 Advantages of Randomized Clinical Trials

- They provide the best evidence that the intervention being studied is causally related to the outcomes of interest.
- The process of randomization minimizes patient selection bias.
- The prospective and concurrent nature of the data collection allows further minimization of bias through blinding, standardization, and quality control of measurements.
- The design, execution, and reporting for clinical trials allow standardization and more detailed and accurate critical appraisal than observational study designs.

which many journals adhere ensures that those aspects that inform critical appraisal are clearly described during reporting (2,3). These guidelines are also now being used by investigators in the planning of clinical trials, and some funding sources require protocols to be submitted in a CONSORT format. Since clinical trials have a more influential contribution to recommendations and evidence-based clinical care, they are subject to more regulation. Institutional ethics boards may have more explicit criteria by which they assess and approve clinical trials. Regulatory agencies may also be involved, such as the U.S. Food and Drug Administration.

WHY ARE THERE NOT MORE CLINICAL TRIALS?

While clinical trials provide the best evidence, there are challenges that preclude many trials from being performed.

TABLE

78.4

Criteria for Defining Causality in Relationships between Interventions and Outcomes

- Is the relationship biologically plausible in terms of the current state of knowledge regarding pathophysiology?
- Is the relationship strong?
- Is the temporal relationship correct? (i.e., Does the intervention precede the development of the outcome or condition?)
- Is there evidence for a dose–response relationship between the intervention and outcome?
- Is the relationship specific for the intervention and outcomes of interest?
- Is the relationship consistent across variations in study populations, settings and investigators, and design?
- Is the relationship free of known and potential confounding?
- Is the relationship free of systematic and random measurement error?
- If an intervention is successful in reducing or eliminating a particular risk factor or causal mechanism for an outcome, does this then alter the outcome in a consistent and predicted manner?

Resource Requirements and Conflicts of Interest

The execution of clinical trials often requires a lot of resources, and almost invariably cannot be performed without some external funding. Often, this funding may come, wholly or in part, from industry. The relationship with industry brings up issues of real and perceived conflicts of interest, when the industry sponsor or partners have a financial interest in the results of the trial. This may also be true of nonindustry funding sources.

Equipoise and Execution

The logistics of designing and executing a clinical trial are often greater than those of performing an observational study. Equipoise must exist at the beginning and throughout the study period, meaning that the investigators must be convinced that there is insufficient evidence regarding the superiority or equivalency of one intervention over another or standard of care, otherwise it would be unethical to withhold the superior intervention from subjects. Investigators must agree to follow a common protocol, that measurements must be performed to a given standard, and that every effort is made to ensure that data collection is complete and subjects are not lost to follow-up. Often additional quality control measures are necessary, including data coordinating centers, data coordinators, core laboratories, and data and safety monitoring boards (DSMBs).

Feasibility

A major factor that keeps many important clinical trials from being performed is lack of feasibility. This is most often

because there are insufficient participating subjects. This may be as a result of the clinical condition being rare with few available potential subjects, necessary but restrictive inclusion and exclusion criteria limiting the number of eligible subjects, poor recruitment or consent rates, or the outcomes being tracked are rare or take exceedingly long to become manifest. Another feature about clinical trials that informs feasibility is that one can only study a limited number of interventions, usually only two or three, within any given single trial.

Failure of Assumptions

Clinical trials are risky endeavors. One usually begins with a hypothesis, around which assumptions are made based on available preliminary trials, observational studies, extrapolations, or educated guesses. These assumptions inform how much of a differential effect on a primary outcome attributable to the interventions being studied might be expected or clinically sufficient, and how much variation or error there might be around that effect. Often, well-designed clinical trials fail because these assumptions were incorrect. When a clinical trial shows an effect that is less than anticipated from the hypothesis and often not statistically significant but still potentially of clinical relevance, or the variation around the effect is such that one cannot be confident that one has excluded a clinically relevant effect, then the results of the trial fall into a “no man’s land,” being neither definitively positive or definitively negative.

Publication Bias

The results of negative and inconclusive clinical trials are less likely to be published and contribute to the body of evidence. The absence of these trials from the published evidence leads to an unbalance toward trials with positive results, the so-called “publication bias.” The current requirement for clinical trials to be registered with a cataloging service within the public domain before starting recruitment is an attempt by journal editors to prevent this bias, as well as to make participation in clinical trials more widely available to potential subjects (4).

Specialty-specific Challenges

There are a number of challenges regarding clinical trials specific to pediatric and congenital cardiology and cardiovascular surgery, as outlined in Table 78.5. One of the major advances in overcoming some of these obstacles was the funding and formation in 2001 of the Pediatric Heart Network by the U.S. National Institutes of Health, National Heart, Lung and Blood Institute (5). The Pediatric Heart Network is a consortium of leading North American pediatric cardiology programs, together with a data coordinating center, aimed at performing multi-institutional studies, and has successfully completed some landmark clinical trials(6–9).

DESIGN ISSUES FOR CLINICAL TRIALS

Both the design and execution of a clinical trial can have a strong influence on the degree to which the findings from the completed study represent the truth in terms of the answer to the research question (Fig. 78.1). Errors in the design and execution may compromise the degree to which the findings have validity, reliability, and generalizability. Errors in the execution can influence the degree to which the findings from

TABLE 78.6 Phases of Clinical Trials

Phase I Usually an uncontrolled study
Determine dosage and administration of the intervention associated with safety
Evaluate short-term safety and tolerability of the intervention
Provide preliminary data on efficacy
Phase II Smaller scale controlled study
Refine optimal dose and administration associated with potential efficacy
Determine common short-term adverse effects and risks
Provide further data to inform feasibility and design of larger efficacy trials
Phase III Randomized clinical trial
Determine clinical efficacy or effectiveness and safety parameters
Phase IV Usually long-term surveillance or specific clinical trials
Determine efficacy and effectiveness regarding long-term outcomes
Determine long-term safety and track rare adverse events
Investigate the intervention in more specific populations, such as children

intervention and determining feasibility, to more definitive determinations of efficacy, effectiveness, and safety. Each phase provides preliminary data and evidence to inform the next phase, creating a body of evidence that will eventually inform recommendations and evidence-based clinical decision making. These phases are particularly applicable to interventions involving investigational new drugs and devices, and proceed in a defined sequence, as noted in Table 78.6. The aims of each phase are different, and inform the choice of approach and study design. Given that large scale efficacy and effectiveness trials are risky endeavors, these phases help to ensure that sufficient rationale and preliminary data inform their design and execution.

Phase I studies are usually the bridge from experiments in animal models to human subjects. For drugs, these studies are usually conducted with healthy volunteers, although they may be conducted with patients to whom the drug may be of benefit or for whom conventional therapies have failed. Phase I studies are usually not randomized or controlled (no comparison group), are small in scale, and are aimed at determining short-term safety and tolerability, dosing (including the maximally tolerated dose and toxicity) and administration through pharmacodynamic and pharmacokinetic testing, and preliminary results regarding effectiveness.

Phase II studies are based on the results from phase I studies, and are aimed at determining whether or not the intervention will have an effect on the outcomes of interest in the population to whom the intervention will be applied in clinical practice. Usually these are smaller randomized and controlled clinical trials, and the primary outcomes may be more mechanistic in nature. Phase II studies also may lead to refinements in dosing and administration, and determine short-term adverse effects and risks beyond those noted in the Phase I preliminary studies. Phase II studies will help to determine feasibility and to provide important information about assumptions around the hypothesis that will be tested in Phase III studies.

Phase III studies are aimed at providing robust evidence for clinical efficacy or effectiveness, while further specifying safety. These studies are meant to satisfy regulatory requirements for industry prior to marketing a drug or device, and are used to inform clinical recommendations and evidence-based practice. Phase III studies are rigorous randomized controlled clinical trials with large numbers of subjects, and tend to have a shorter intervention or follow-up period than would be used in clinical practice. These trials are powered to detect a clinically meaningful impact on an outcome that is immediately relevant to the patient, such as mortality, symptomatic morbidity, and functional health or quality of life. These outcomes are much harder to study in children and congenital heart patients, where the outcomes occurring are less frequent, occur over a longer period of time, or are less well-conceptualized.

Phase IV studies are long-term studies or surveillances conducted after the drug or device has received regulatory approval and is being marketed. They are aimed at monitoring the incidence of adverse events, particularly those that are rare, and to determine long-term effectiveness and safety. Phase IV studies are usually registries, although they may include clinical trials, particularly if they are aimed at determining efficacy, effectiveness, and safety for more specific indications or in more specialized populations (such as children or congenital heart patients) than in the Phase III trials.

Questions, Hypotheses, and Aims

The conceptualization of all clinical trials begins with a question. The specification of that question is founded on a sound knowledge base and preliminary evidence that leads one to a specific and focused area of controversy or uncertainty. A focused question will define the study population, the intervention and comparison, and the primary outcome for the clinical trial. The process of specification of the question forms the rationale for the clinical trial that is proposed.

The rationale informs the background/preliminary studies section of study protocols and the introduction section of manuscripts. The rationale is not merely an exhaustive literature review, but should represent a synthesis, and like any good story, should have a climax and a point. A well-conceived background to a proposal also represents the starting point for the discussion section of a manuscript once the study results are determined. In outlining these sections, one usually begins by defining the broad topic area, and then honing down to the specific area of controversy or uncertainty. The rationale is provided from both the published literature and preliminary work by the investigators. The rationale is based on the identification of deficiencies in previous studies, conflicting or paradoxical results, gaps in knowledge, or gaps in evidence. The rationale should lead directly to a statement of the research question (stated as a question), which leads to a statement of the primary aim of the trial (the question rephrased as an action item).

The relevance and significance of the question being pursued is another important aspect of the rationale. It defines the importance of the question, which is dependent on the importance of a truthful answer. Put simply, the potential answer must pass the “So what?” test. There are many dimensions to relevance and significance, which can be qualitatively or quantitatively supported. The answer may provide evidence leading to further lines of inquiry, may impact the care of patients, leading to reductions in disease burden or risk, or improvements in patient level outcomes, or may inform clinical recommendations, guidelines, or health policy. The answer should be both interesting and novel.

A *hypothesis* is the best guess as to what the answer to the study question might be. It should ideally be based on knowledge of the published literature and preliminary work and, hence, be an informed guess. The hypothesis should be specified at the same time that one poses the study question, which should be before any data are collected. It should also be detailed and specific to the study subjects, the intervention, and the direction and magnitude of effect on the primary outcome. Hypotheses should similarly be prespecified for each secondary research question. For the purposes of sample size estimation and inferential statistical testing, the hypotheses must be restated in a different manner, to be discussed in a later section of this chapter.

Study aims represent the main and secondary study questions, but are rephrased as an action item. As such, they are like mission statements, which define the direction or design of the clinical trial. The primary study aim should include the defining characteristic of the study population, the intervention and comparison being studied, and the primary outcome (the main or most important outcome). The design of the trial should be specific to achieve this primary aim. Sample size calculations to estimate the number of subjects required are based on the primary aim and an associated hypothesis, together with statistical considerations specifying the risk tolerance for random errors. Secondary aims are usually structured around subgroup comparisons, other types of outcomes, and mechanistic explorations. Secondary aims and hypotheses should be relevant to the primary aim, but provide a greater degree of breadth and depth to the study, which can increase the relevance and significance of a trial. One does not usually hinge sample size calculations on these secondary aims and hypotheses, but one can calculate the degree of power that may be available to test the hypotheses reliably.

Primary and secondary outcomes should be clearly specified and justified and relate directly to the study aims and underlying research questions. In the design phase of clinical trial development, much consideration is usually given to choosing the primary outcome. Preference is usually given to outcomes that are of direct relevance to the patient, with mortality being the outcome of utmost importance. Other relevant outcomes might be morbidities that impact on patient well-being, risk of intervention or further reintervention, and, more recently, assessments of functional health status or health-related quality of life. A hypothesis regarding the differential impact of the study interventions on the primary outcome informs the sample size calculations specifying the number of subjects required. Secondary outcomes are outcomes of interest that may be related to the primary outcome, either by association or informing a mechanistic relationship. The most common secondary outcomes are measures of adverse effects or events, pathophysiologic parameters, or health care system factors, such as utilization or costs.

Interventions and Clinical Trial Designs

The choice of intervention(s) and comparison should be evident from specification of the research question and primary aim, as well as the phase of investigations as described previously. All aspects of the intervention and its application (what, how, when, where, who) should be considered and exactly specified in advance. In pediatric trials, particular attention should be given to dosing and formulation, and to monitoring for adverse effects. The strategy for ensuring and monitoring of compliance should be detailed. The specification of the interventions should be such that they can be replicated and applied in further studies, adapted to different populations and scenarios, or implemented in clinical practice. These details should be provided in the study protocol, the manual of

operations, and in any subsequent publication of the methods and/or the results of the trial.

Choice of the comparison group can be a key factor in the design of clinical trials. If aspects of the application of the intervention are likely to be influencers of outcomes or to unblind the allocation assignment, then precautions should be taken to have as many aspects as possible replicated identically for the comparison. This may include identical formulation and application of study drug and placebo, or the use of sham procedures. Often, particularly for pediatric patients, the undue burden of taking placebo or undergoing sham procedures cannot be supported due to ethical concerns. Additionally, there may be ethical concerns if there is a reasonable standard of care or alternative that may be withheld. These considerations become key drivers in the design of clinical trials in pediatrics.

The approach or perspective of the clinical trial is linked to the primary aims. Some clinical trials aim to determine if one intervention is better or safer than either usual or standard care, placebo or nonintervention, or an alternative study intervention (superiority trial). While the majority of clinical trials are undertaken with the hypothesis that the intervention of interest will be shown to be better (a one-tailed approach), statistical testing of that hypothesis is conventionally performed with a supposition that the intervention of interest may also be shown to be worse (a two-tailed approach). The two-tailed approach underlies inferential statistical testing, but it also has merit in that many interventions supported by observational studies and preliminary data are subsequently shown to be either equivalent or inferior to their comparison in a large-scale phase III trial. Alternatively and less frequently, some clinical trials aim to determine whether one intervention is no better or worse than either usual care or an alternative study intervention (non-inferiority or equivalence trial). These trials are relevant when a new intervention has advantages over an established or alternative intervention (reduced costs, greater availability, improved feasibility, better tolerance, and acceptability) but there is a need to establish that outcomes will be at least equivalent and noninferior. The threshold for defining noninferior depends on the advantages of the new intervention, and there may be a trade-off for accepting some decrease in efficacy.

Simple randomized clinical trial, also called parallel group design, is the most common clinical trial design. It is characterized by subjects being recruited and randomized concurrently to only one of either an intervention or comparison, and followed concurrently to a specified single study end point. This design is the easiest to implement and to critically appraise, and is also somewhat flexible. It is limited in that it only allows one to study the relative effect of one intervention at a time.

Crossover clinical trials are a variation of the parallel group design whereby subjects are first randomized to either the intervention or comparison for a specified period of time, and then reassigned to the opposite of the initial allocation for a second specified period of time. It allows each subject to receive both intervention and comparison in randomized order. It is often used when the number of study subjects is limited and when the outcomes occur over a relatively short period of time. It allows both within group and between group comparisons, with each subject acting as their own control or comparison, which also helps to minimize bias and allows for paired analyses. Besides increased logistical issues, one of the major limitations of this design is the problem of dropouts, since the subjects are followed longer, have increased exposure to adverse effects, and may not wish to continue with a second period of possible placebo or a less-desirable alternative. Another limitation is the potential for carryover effects, whereby the effects of the initial intervention continue to operate over the second period to influence outcomes. One method

to help prevent carryover effects is to have an appropriate washout period between study periods, although this may be ineffective and further lengthen the study and contribute to dropout. Both of these limitations complicate the analysis and interpretation of the trial results.

A *factorial design* allows the study of more than one intervention together (interaction) as well as separately (independent). The least complex factorial design randomizes subjects to one of four groups—neither intervention (comparison), both interventions, and each intervention separately—and is called a 2×2 factorial design. This design can be efficient in determining both the individual and combined benefits of interventions, including synergy, but also carries the risk of unexpected adverse effects from the combination. Factorial design trials require larger numbers of subjects and have greater logistical issues, and the analysis and interpretation can be complex.

Study Subjects

The degree to which the study subjects enrolled and completing the trial are representative, meaning similar in characteristics and response, of all applicable patients depends on specific aspects of how those subjects were chosen, recruited, and maintained as participants in the trial. These aspects can have important impacts on the validity of the results and their generalizability, and are outlined in Table 78.7.

Definition of the study population begins with examination of the aims and hypotheses of the clinical trial. One wishes to infer that the results of the trial for those subjects studied will be representative of the truth if the trial had been performed in the universe of potential subjects, or the target population. It is usually given that one cannot study absolutely everyone, but one can study those potential subjects who can be identified and approached by the investigators, or the accessible population. Of the accessible population, some subjects cannot be contacted, will prove not appropriate for study, may decline to participate or may start but not complete their participation, and represent the actual study subjects. The degree to which,

at each stage, the subjects are similar to the target population will inform the validity of inferences based on the results from the actual study subjects.

Inclusion and exclusion criteria are defined to refine specification of the accessible population that may be recruited for study participation. Inclusion criteria are the defining characteristics specific to the target population applicable to the study aims. They usually include demographic characteristics (age, sex), clinical characteristics (anatomy, diagnoses, morbidities, procedures), accessibility characteristics (geography, settings), and the time period. Exclusion criteria are characteristics that may influence participation (language barriers, anticipated poor compliance or follow-up, cognitive or physical limitations), applicability or safety of the study interventions (contraindications), or unduly influence outcomes (associated conditions or treatments). Each criterion should be exactly and objectively defined as far as possible. There must be an appropriate balance between being too general and too overly restrictive, balancing generalizability with feasibility.

Sampling strategies may sometimes be necessary when the number of accessible and potentially eligible subjects exceeds the number of subjects required, but one wishes to minimize selection bias. Convenience sampling is most liable to potential bias, and involves selecting subjects who are the most accessible, such as enrolling subjects as they present from routinely scheduled clinic visits. Systematic sampling involves having a system to select subjects, such as enrolling no more than four subjects per week from the surgical list. Simple random sampling involves creating a list of all accessible subjects and then selecting subjects at random until the desired number is achieved, and is the method most likely to minimize selection bias. Random sampling can be stratified by dividing the accessible subjects into defined subgroups, and then sampling within those subgroups, and may be used when the investigators wish to examine the differential effects of the study interventions. If used, any sampling strategy must be exactly specified and tamperproof.

Study Measurements

In any clinical trial, a large amount of data will be collected at various time points throughout the study and for various purposes. Each individual piece of information will play different and sometimes multiple roles in helping to define truth in the results and inform the interpretation and appraisal of the evidence emerging from the clinical trial. The purpose and measurement properties of every variable should be justified and specified in the design of the trial. Each variable can be specified according to several different classifications, as outlined in Table 78.8.

The purpose or rationale provides the justification for inclusion of each measurement or variable. Measurements can be used to characterize the study subjects for description, and should include data collection that verifies inclusion and exclusion criteria. Particularly for procedural study interventions, data should be collected about the execution of the intervention and both concomitant and subsequent management. Outcome variables can be assessed prior to randomization, to either ensure study subjects are free of the outcome or to provide a baseline measure against which subsequent change is assessed. Variables that can confound the relationship between the study interventions and outcomes should be assessed. Confounding occurs when the relationship between the intervention and the outcome is actually due to another factor that is not associated with the intervention. In clinical trials, randomization minimizes the chance of confounding by balancing these factors between intervention and comparison groups. Variables that may interact with the

TABLE 78.7 Defining and Selecting the Study Subjects

- Identify the characteristics of the population to which you would wish to apply the results of the completed trial.
- Identify the population of subjects that are available and accessible for potential recruitment.
- Define the inclusion and exclusion criteria that will specify eligibility for participation.
- If the number of available subjects exceeds the number required, identify an appropriate sampling strategy.
- Define the recruitment and consenting strategy.
- Define strategies for minimizing dropouts and loss to follow-up.
- During execution of the trial, carefully track subject numbers, any available subject-level information, and reasons for exclusion, failed recruitment or consent, and subject loss.
- During data analysis, explore available information to detect any differences or potential bias between participants and nonparticipants at various stages of selecting, enrolling, and studying the subjects.

TABLE 78.8

Characteristics of Study Measurements or Variables

- Purpose or rationale for the measurements or variables
 - study subject characterization
 - study intervention characterization
 - outcome variables
 - potential confounding variables
 - potential interaction variables
- Nature of the measurements
 - Time-related events
 - cross-sectional measures
 - repeated or serial measures
 - qualitative assessment
- Timing of the measurements during study execution
 - at baseline before randomization
 - during study execution
 - at study period endpoint
- Properties of the measurements
 - validity and systematic error
 - reliability and random error
 - level of measurement
 - nominal
 - ordinal
 - interval
 - ratio

study interventions in influencing outcomes should also be considered. In clinical trials, this is the rationale justifying prespecified subgroup analyses, whereby the investigators are determining if the effect of the intervention on the outcome is modified by the presence of other factors. Usually, subgroup analyses in clinical trials are considered exploratory and hypothesis generating, and are often not sufficiently powered to be definitive.

The nature of the measurements, particularly of the outcome variables, influences how sample size should be calculated and how the data will need to be handled during data analysis. Most primary outcomes in clinical trials will be events that are associated with a variable period of time, such as death, morbidities, or procedures. Survival or timed-event analyses are required. Some outcomes are measured after a specific period of time after randomization and study intervention, where the final measurement is cross-sectional in nature. Intervention group comparisons are made at that time point, but may be adjusted for baseline assessment or other potential confounders in multivariable regression analyses. Some outcomes are made repeatedly throughout the period of observation, usually at prespecified time points, and one is interested in determining the difference in trends between groups. Repeated measures or longitudinal regression analysis techniques are required. Less frequently, the outcome of interest is of a qualitative nature, such as responses from a structured interview. Techniques for identifying themes within transcripts of these interviews can be used, and the themes compared between groups.

The timing of measurements during study execution is an important consideration, and is linked to the rationale for that measurement. Some data are collected at baseline and then repeatedly during study execution, and are usually secondary outcome measures such as adverse effects. Other data may be collected only at baseline, such as descriptive or potential confounding variables, or only at study endpoint, such as outcome measures.

Various properties of the measurement need to be considered when planning the measurements and defining what data are to be collected and in what format. An important property is the validity of the measure, or the degree to which the measure is an accurate reflection of the concept of what one is trying to measure. This is particularly of importance when one is trying to measure concepts that are more subjective in nature, such as functional health status or symptom severity. The greater the degree of subjectivity of a measurement, the greater is the risk of systematic error. To some extent, systematic error is a component reflected in intraobserver and interobserver variability. Another property is reliability, or the degree to which you get the same result if you measure the same thing in the same way on the same subject or specimen. Reliability is influenced by random error as well as systematic error. Both systematic and random errors can be reduced with increased quality control over performance and interpretation of the measurements.

Level of measurement is another property that influences sample size calculations and data analysis techniques. Some measures are nominal in nature, meaning that the values are in discrete, unordered, and mutually exclusive categories. An example would be type of device placed for transcatheter atrial septal defect closure. Some measures are ordinal in nature, with the values also in nominal categories but with a non-quantifiable gradient relationship between them. An example might be grading of aortic regurgitation as none, mild, moderate, and severe. Continuous interval variables are those whose values are more infinite and have a quantifiable gradient. An example might be weight or temperature. Ratio variables are continuous variables that vary over a discrete range defined by a denominator, such as percent oxygen saturation. In general, using continuous measures can reduce sample size requirements, and allow determination and specification of dose-response relationships between variables.

Randomization

In clinical practice, patients receive interventions based on specific characteristics, which may include clinical variables, practice variables, and patient and provider preferences. Some of these characteristics influence outcomes, independent of or in interaction with the intervention received. This introduces error when comparing outcomes after interventions. Ideally, one would like to be assured that any differences in outcomes were solely attributable to the interventions being compared. Differences in baseline characteristics can be minimized if the subjects are randomly allocated to intervention groups, hence eliminating selection bias. Random allocation gives the best chance that baseline differences will be minimized, including differences in both measured and unmeasured characteristics. The greater the number of subjects randomized, the greater the likelihood that there will be few important differences in characteristics between the groups. One can also test the success of randomization, by comparing the measured baseline characteristics between assigned intervention groups and by looking for both potentially relevant and statistically significant differences. In analyses of outcome comparisons, one has the opportunity for applying statistical adjustment for any or all baseline characteristics.

TABLE 78.9 Requirements for Valid Randomization

- Ensure that the generation of the allocation schedule is truly random by using random number tables or computer algorithms.
- Ensure the sequence is not predictable, but that the method can be replicated.
- Have the process of generation of the allocation schedule performed and maintained independently from those implementing the study.
- Ensure that the allocation schedule is tamperproof, and that assignment is masked to the subjects and study personnel until the intervention is to be applied or started.
- Allocation of assignment should only be made or unmasked after subject eligibility has been confirmed, consent obtained, baseline measures completed, and at the time the intervention is to be applied or started.
- Ongoing masking or blinding of assignment for subjects, study personnel, and those performing data analyses should be in place, as appropriate for the specific study, and be tamperproof.
- Ensure that the assignment process is clearly documented and tracked for quality control.

Valid randomization can only be achieved if it is performed and applied properly, as noted in Table 78.9. This is achieved when allocation is truly random and when it is tamperproof.

Variations of randomization can be employed for specific purposes, as noted in Table 78.10. Most large trials employ simple randomization, as the large number of subjects minimizes

the chance of random imbalances in characteristics between groups. Use of blocks with simple randomization ensures that the number of subjects in each group is equal at the start of the intervention throughout the study. Cluster randomization is used when subjects fall into natural groups where there might be contamination between individuals within the groups if they were to receive different interventions, such as an educational or behavioral intervention. Some randomization variations are employed to ensure that there are no chance differences between groups regarding specific baseline characteristics that have an important influence on the outcomes, and included stratified randomization and pair matching.

Controversial variations of randomization include unequal allocation and adaptive randomization. Unequal allocation entails allocating more subjects to one group than another, usually in a specific ratio other than 1:1, creating groups of unequal sizes. It may be used to evaluate multiple treatment groups against a single control group, with relatively larger numbers allocated to control. Increased allocation to an intervention group may be desired to detect rare outcomes and adverse effects specific to that intervention. It may be used to increase recruitment when it is known that subjects have a greater chance of being allocated to a desirable intervention. Conversely, it may be used to limit allocation to an intervention that is expensive or of limited availability. This type of allocation reduces statistical power, complicates consent, and remains controversial as to validity. Adaptive randomization entails changing the probability of allocation for the next subject based on the characteristics of those subjects previously randomized. This can be used as the allocation proceeds to correct for imbalances regarding baseline characteristics (covariate adaptive) or differences in group sizes (treatment adaptive). It may also be used to preferentially assign subjects to the “best” intervention based on the outcomes of preceding subjects, allowing more subjects to be given the potentially beneficial intervention, or fewer subjects to be given a potentially harmful or ineffective intervention. Adaptive allocation requires continuous tracking of characteristics and outcomes,

TABLE 78.10 Types of Randomization

	Method	Advantages	Challenges
Simple randomization	Allocating subjects independently, sequentially, and randomly to intervention groups with no consideration as to previous allocations	Simple, efficient, sufficient for large trials	May result in imbalances in numbers and characteristics when applied in small trials
Block randomization	Simple randomization with the subjects being allocated within blocks of a specified but preferably random size	Ensures an equal number of subjects in each group at the end of allocation of each block	Use of fixed block sizes may allow for prediction of sequential assignments
Cluster randomization	Subjects allocated as clusters, with groupings based on specific characteristics, e.g., families, schools, clinics, communities	Reduces contamination bias between individuals in the same cluster, as they all receive the same intervention	Applicable only to large trials and must be sufficient clusters; analyses must consider inter- and intracluster variation and effects
Stratified randomization	Block randomization according to potentially influential baseline characteristics where equal allocation must be assured	Ensures there is no imbalance between groups regarding the specific influential baseline characteristic	Increases complexity; can only practically have no more than one to three stratifying variables
Pair matching	Subjects are paired at baseline according to matching characteristics, and then the individuals in the pair are randomly assigned to the intervention groups	Ensures there is no imbalance between groups regarding those characteristics used to match subjects	More potential subjects needed to make good matches; increases complexity; requires analysis of pairs

often precludes effective blinding, and reduces statistical power and validity.

Cointerventions and Blinding

A significant factor that may alter, or confound, the results of a clinical trial is cointervention, a phenomenon that occurs when potentially outcome-altering interventions (other than the study intervention) are administered to some subjects, but are not specified in the study protocol. Cointerventions may be introduced into the study intentionally or unintentionally, and are often allocated to subjects by nonrandom means. For example, if investigators believe the study intervention to be effective, they may (consciously or unconsciously) give compensatory care to those not receiving the intervention in the control group. Conversely, subjects in the study intervention group may take extra steps to supplement or augment any intervention effect, to increase the likelihood of an anticipated outcome. Such behavior results in uneven distribution of cointervention across trial groups, and subsequent confounding of the trial outcome.

Ascertainment or reporting bias is another important confounding behavior in clinical trials, wherein study investigators or subjects may have an altered perception or reporting of outcomes due to knowledge of the subject's group assignment. For example, an investigator may become more likely to seek and declare a positive outcome measure when aware of a subject's assignment to the study intervention group.

Blinding or masking can minimize both cointervention and ascertainment bias in clinical trials. When blinding, either the study subjects, investigators, or both are made unaware of the intervention assignments until the end of the trial, as outlined in Table 78.11. Triple blinding adds blinding to any data analyses, whereby those performing or reviewing interim and final analyses for either safety or for efficacy are unaware of the meaning of the groups, that is, the groups are labeled A and B. Regardless of the degree of blinding of subjects and investigators, any individual charged with measuring the primary outcome of a trial should always be blinded to the greatest extent possible. This includes any laboratory personnel analyzing study samples, as well as clinical staff charged with interpreting any data susceptible to significant interobserver variability, as outlined in Table 78.12.

Use of placebo systems can facilitate blinding. Placebos are an inert or sham intervention designed to mimic the study intervention in all but biologic effect, and would be administered to the control or comparison group of a clinical trial. Placebo controls serve to make the study interventions indistinguishable to both subjects and investigators, maintaining blindness to individual group assignments. Placebos should, therefore, be matched to the study intervention in as many dimensions as possible. In certain cases, placebo use may be restricted by ethical or logistical limitations, forcing the trial

TABLE 78.11 Types of Blinding in Clinical Trials

■ Unblinded	Both subjects and investigators are aware of group assignments. Sometimes necessitated by logistical and ethical constraints. Most susceptible to cointervention and ascertainment bias.
■ Single-blinded	Only the subjects are unaware of the group assignments.
■ Double-blinded	Both subjects and investigators are unaware of assignments. Gold standard of clinical trial designs. Least susceptible to cointervention and ascertainment bias.

to follow a single-blind or unblinded design, as outlined in Table 78.13.

Unblinding of a subject's intervention assignment may be necessary in certain emergency circumstances, such as the presence of a severe adverse effect or some unrelated emergency requiring intervention that may interact with their study intervention. Since such circumstances often evolve suddenly, safety measures should be put in place to allow for quick and accurate unblinding in the case of such an event. Such measures might include distribution of a 24-hour emergency telephone number to all subjects through which their care providers may access immediate unblinding. The decision to break blinding to any extent directly impacts the validity of any trial results, and should only be considered when deemed essential by the subject's treating care provider. Where possible, the level of unblinding should be kept to a minimum. One can often unblind to the treating care provider without disclosure to the subject or investigators.

Success of blinding throughout a trial can be evaluated at the end of a study by a simple survey, asking subjects and investigators to make guesses on group assignments. If >50% of guesses are correct for either subjects or investigators, then the blindness of the study may have been compromised.

Sample Size and Power

A pivotal component of clinical trial design is an estimation of the number of completing study subjects needed in order to reliably achieve the study aim and confidently answer

TABLE 78.12 Influence of Outcome Type on Blindness of Study Design

Outcome Type	Definition	Example	Implications
Subjective	Ascertainment requires a subjective judgment on the part of an observer.	Outcome determined by diagnosis based on interpretation of echocardiography.	High risk of ascertainment bias. Trial should be blinded to the greatest possible extent.
Nonsubjective or binary	Ascertainment does not require a subjective judgment.	Mortality as a study end point.	Low risk of ascertainment bias. Full blinding may not be strongly required, but the highest feasible degree of blinding is recommended.

TABLE 78.13 Limitations on Placebo Use in Clinical Trials**Ethical Limitations****Studies investigating severe conditions**

Withholding of active intervention through placebo use may pose unacceptable risk to subject safety.

Studies evaluating surgical interventions

Performance of sham surgeries on the control group may be unethical, due to high risk and invasiveness.

Consent issues

Subjects must be made fully aware of the likelihood of assignment to placebo, which may not be feasible with certain types of interventions.

Logistical Limitations**Difficulty in intervention matching**

Due to properties of the active intervention; for example:

Distinct color, taste, or smell

High risk of distinct side effects

Highly specific administration procedure

the research question. If too few subjects are studied the possibility of erroneous conclusions is increased; if too many subjects are studied there is greater cost and loss of efficiency. The required number of subjects who completed participation in the trial and had valid outcome assessment is a subset of the subjects who were enrolled and allocated to the study interventions, which is a subset of accessible subjects who were deemed potentially eligible, which is a subset of the target population to whom one wishes to generalize the trial results. One would like to be confident that one can infer that the results of the study as performed in the participating subjects is a reasonable reflection of the results had the study been performed perfectly with the entire target population, and hence, are the truth.

The calculation of sample size is always based on a number of assumptions, and must, therefore, be viewed as an estimation. The necessary components to calculate sample size are hypotheses that include an estimation regarding an anticipated and clinically relevant effect size and its variation, and specification of tolerance limits for making potentially erroneous conclusions, as outlined in Table 78.14.

The null hypothesis is derived from the research hypothesis but states that there will be no difference in the primary outcome between the study intervention and comparison groups. The null hypothesis forms the basis for formal statistical testing, and in superiority trials, the goal is to reject this hypothesis with a certain level of confidence that a clinically relevant difference is likely. In inferiority trials, the goal is to accept this hypothesis with a certain level of confidence that a clinically relevant difference is unlikely.

The alternative hypothesis is the converse of the null hypothesis, stating that a difference or effect will be present. The alternative hypothesis is accepted if the observed results favor rejection of the null hypothesis. The alternative hypothesis can be stated such that the effect will only be in one direction, either a benefit or decrement, which is referred to as a one-sided hypothesis. The convention is to simply state the alternative hypothesis such that an effect exists, but that it could be in either direction, which is referred to as a two-tailed hypothesis.

The effect size and its variation are a further specification of the alternative hypothesis. The specification of the primary outcome, effect size, and variation are the most challenging components of designing a clinical trial, since they may lead to sample size estimates that render a trial not feasible or relevant, or lead to results that are subject to error and inconclusive. The estimation of effect size and variation should be based on as much relevant information as is possible. This can come

from the published literature, and from smaller pilot trials or observational studies. Ideally, one should specify an effect size that has clinical significance or importance. For superiority trials, clinical importance is defined as the minimum effect size in the direction of benefit attributable to the study intervention that would justify preference for that intervention in clinical practice. For inferiority trials, clinical importance is defined as the minimum effect size in the direction of lack of benefit that would justify abandoning the intervention as an alternative in clinical practice.

TABLE 78.14 Requirements for Estimating Sample Size

- State a null hypothesis specifying no difference in primary outcome between the study intervention and comparison groups.
- State an alternative hypothesis specifying that there will be a difference in the primary outcome between groups.
- Specify whether the expected difference in the primary outcome can be in one direction only (one-sided) or can be in either direction (two-sided).
- Specify the magnitude of the expected difference or effect size, and estimate the degree of variation or random error around that difference.
- Specify the tolerance (alpha) for incorrectly concluding, based on the observed results of the study, that there is a relevant effect size when in truth there is none (type I error—erroneously reject the null hypothesis).
- Specify the tolerance (beta) for incorrectly concluding, based on the observed results, that there is no relevant effect size when in truth one is present (type II error—erroneously accept the null hypothesis).
- Specify the method for calculation of sample size, based on the statistical test, to be applied for comparison of study groups according to the nature and level of measurement of the primary outcome.

The tolerance for erroneously rejecting or accepting the null hypothesis based on the observed study results also informs sample size estimation. A type I error entails incorrectly rejecting the null hypothesis and concluding that a significant difference or effect exists based on the results in the observed sample, when in truth, in the target population there is no effect or difference. This is also referred to as a false positive. The tolerance for making this error based on probability theory and random chance is referred to as alpha. In general, the convention is to accept a 5% chance of making this error, or specifying an alpha of 0.05. Alpha is also referred to as the level of statistical significance, and is analogous to the *p*-value of inferential statistical testing. A type II error entails incorrectly accepting the null hypothesis and concluding that there is no significant difference or effect when in truth one exists. This is also referred to as a false negative. The tolerance for making this type of error is also based on random chance and referred to as beta. In general, the convention is to accept a 5% to 20% chance of making this error, or specifying a beta of 0.05 to 0.20. The flip side of beta is power, or 1-beta, which is the probability of correctly rejecting the null hypothesis based on the observed results and concluding that an effect equal to

or greater than that observed in the study actually is truly present in the target population. Power calculations take on importance when considering anticipated effects on secondary outcomes and related hypotheses, or when the observed results regarding effect on the primary outcome are less than hypothesized or the variation is greater, and one lacks the confidence to reject the null hypothesis.

The method of calculation of sample size is specified by the number of study groups and the nature and level of measurement of the primary outcome that determines the probability distribution for testing. This determines the statistical test to be applied when comparing the primary outcome between study groups. An example of a worked calculation of sample size from a specific study is outlined in Table 78.15, based on a clinical trial of thromboprophylaxis in Fontan patients (10). Formulas and tables for estimating sample size and calculating power are available in many textbooks, and online calculators are available on many websites. For complex study designs and outcomes, including time-related events, longitudinal data, or multivariable regression, consultation with a statistician is usually required. Being able to specify the requirements outlined in Table 78.14 will greatly facilitate the statistician in choosing the appropriate methods for calculation.

TABLE 78.15 Worked Example of Sample Size Calculation

Scenario: A 2-year open-label randomized clinical trial was performed on patients undergoing Fontan procedure. Patients were randomized after Fontan procedure completion to either low dose acetylsalicylic acid (ASA) or a heparin lead-in followed by warfarin to maintain an international normalized ratio (INR) between 2.0 and 3.0. The primary outcome was the presence of thrombosis or occurrence of a thrombosis-related event occurring over a 2-year period, with scheduled transesophageal echocardiography performed at 3 months and 2 years after randomization and all outcomes being adjudicated.

Sample size parameters:

Null hypothesis: There will be no difference between treatment groups regarding the 2-year incidence of thrombosis/events.

Alternative hypothesis: There will be a difference between treatment groups (two-sided hypothesis).

Effect size: The incidence will be 25% in the ASA group and 10% in the warfarin group, based on a systematic review of published observational studies. A 15% absolute difference was judged to be the minimal clinically important benefit that would justify the inconvenience and risks of warfarin.

Alpha: 0.05.

Beta: 0.20.

Statistical test: Kaplan-Meier timed-event analysis would be used to determine the freedom from thrombosis/event at 2 years for each group, which would, for simplicity of sample size calculation, then be compared using Chi-square.

The calculation:

The formula for estimation of the total sample size *N* (both groups combined) is:

$$N = \frac{[z_{\alpha} \times \sqrt{P(1-P)(1/q_1 + 1/q_2)} + z_{\beta} \times \sqrt{P_1(1-P_1)(1/q_1) + P_2(1-P_2)(1/q_2)}]^2}{(P_1 - P_2)^2}$$

Where

P_1 = incidence in the warfarin group = 0.10

P_2 = incidence in the ASA group = 0.25

q_1 = proportion allocated to the warfarin group = 0.50

q_2 = proportion allocated to the ASA group = 0.50

$P = q_1P_1 + q_2P_2$

z_{α} = the standard normal deviate for alpha (0.05), two-sided = 1.96

z_{β} = the standard normal deviate for beta (0.20) = 0.84

sqrt = square root

Based on this formula and the specified parameters, *N* would be 224, or 112 subjects per group. (Recruitment is then inflated based on estimated dropouts and loss to follow-up)

EXECUTION ISSUES FOR CLINICAL TRIALS

Nearly all of the issues relevant to the execution of the clinical trial protocol can be minimized in the planning and design stages. However, not all issues can be anticipated or prevented, and ongoing quality control and monitoring are required throughout the execution of the protocol. In addition, the trial must be conducted in compliance with good clinical practice. All study personnel should be trained in the ethical conduct of clinical research, privacy and confidentiality policy, and best practices involving tracking and documentation. The Clinical Trials Networks through the Duke Clinical Research Institute provides information and online training in best practices (www.ctnbestpractices.org).

Operationalization

Implementation of a clinical trial begins with obtaining the necessary administrative and ethics board approvals, and ensuring the trial is registered prior to any recruitment. The protocol should be expanded into an operations manual, which outlines in detail the standard operating procedures (SOPs) for rigorous execution of the trial (Table 78.16). Discussions with study personnel should document roles and responsibilities and accountability, together with completion of training in study procedures. Discussions should also occur with clinical staff who might care for study subjects or identify potential subjects for recruitment. Data collection forms and procedures should be finalized, with detailed data definitions. During the conduct of the trial, any amendments to the protocol should be tracked, together with the reasons and approvals. Any deviations from study procedures should also be documented and tracked. Procedures for adverse event monitoring, documentation, classification, attribution, and reporting should be specified. Periodic study site audits may be planned to ensure compliance with SOPs, complete and accurate documentation and reporting, and to troubleshoot local challenges such as low recruitment or consent rates or excessive loss to follow-up.

Recruitment

Recruitment strategies should be tailored to the individual circumstances of the clinical trial and the nature and characteristics of the accessible population. Well-designed clinical trials can fail or be considerably weakened if the desired number of subjects as specified in the sample size estimation are not recruited and retained until study completion. The study

quickly becomes underpowered in its ability to detect confidently the hypothesized outcome difference or effect size. If the number of accessible subjects is excessively large, then successful recruitment of sufficient study subjects is made more feasible. This is enhanced if the accessible subjects are easy to identify and to contact or approach. Recruitment strategies can be enhanced by piloting recruitment procedures and approach related to the specific trial. Barriers to study recruitment and retention for which strategies should be considered to address them are outlined in Table 78.17.

The identification and approach of potential subjects can be made more or less challenging depending on the nature of

TABLE 78.17 Potential Barriers to Subject Recruitment and Retention

Related to the subjects

- Long wait times and inconvenient scheduling
- Uncomfortable with the uncertainty associated with a trial, particularly randomization
- Misperceptions about research and misinformation about clinical treatments or tests
- Unrealistic understanding of the nature and level of required participation
- Other factors, such as disease status (particularly the presence of symptoms or a poor prognosis), very young or very old age (perceived vulnerability), level of education, social circumstances, language barriers

Related to the investigator

- Inability to integrate and balance roles as caregiver and investigator
- Lack of time or sufficient resources
- Presence of competing interests
- Confusion regarding responsibilities
- Underestimation of workload for study execution, including administration

Related to the study protocol

- Lack of equipoise for the study interventions
- Lack of support for the study aims and design
- Complicated and overly tight eligibility criteria
- Complex study procedures that are difficult to follow
- Long studies and studies with frequent visit schedules
- Studies with excessive monitoring or complex dosing/titration schedules
- Interventions associated with poor subject compliance

Other barriers

- Requirement for excessive documentation and reporting
- Administrative and regulatory barriers
- Insufficient financial support or resources
- Overly intrusive monitoring and audit procedures and schedules
- Poor relationship with lead investigators, study sponsors, clinical research organization

TABLE 78.16 Sample Topics Detailed in the Trial Operations Manual

- Description of the patient population to be studied
- Recruitment, enrollment, and consenting procedures
- Standardized definitions of all study parameters and measurements
- SOPs for all trial functions
- Responsibilities of study personnel
- Standardized solutions to any foreseeable issues that may arise, such as emergency unblinding
- Data collection forms and study instruments

the accessible population. Studies recruiting from the general population present more challenges than those studies where recruitment can occur in settings where potential subjects are put in close proximity with investigators, such as clinical settings where regular care is provided for patients with specific characteristics consistent with study subject inclusion criteria. Initial contact can be indirect, such as through advertising or media or mail-outs, where the obligation is then on to the subject to contact the investigators for more information or to volunteer. For clinical populations, the potential subjects are usually known and can be identified from patient lists and databases. Initial contact should come with the permission and involvement of the patient's responsible care provider, usually by a letter of introduction or a face-to-face introduction on the part of that provider on behalf of the investigators and study personnel. Subjects must not be coerced or inappropriately enticed into participation, and have complete freedom to decline with no impact on their relationship or care provided by their treating providers.

Enrollment begins by providing simple yet complete explanations for the reason for the study, the nature of the study intervention and comparison, and the schedule and type of study measurements. Subjects must understand the concept of randomization and protocolized follow-up, and should also have equipoise for the study interventions. They also must be completely informed of all potential benefits and risks or inconveniences associated with participation. Enrollment is facilitated if the study is simple and short with few study visits, study measures are focused and not obtrusive, and there are perceived benefits for the subject, such as an enhanced feeling of altruism, access to new treatments and more specialized tests, access to treatment and care without costs, costs of participation are reimbursed and incentives are provided, and the patient has the potential to benefit from improved outcomes.

Tracking and documentation of recruitment and enrollment is very important. At each step, moving from the accessible population down to subjects enrolled, minimal data collection regarding characteristics can allow one to look for participation bias. One must enumerate the number and, if possible, characteristics of the accessible population. This can be achieved through census statistics or patient databases, and through minimal data collection at the time of approach. Screening logs should be kept. The number of subjects approached and screened should be tracked, and of those the number of subjects who both meet inclusion criteria or have exclusion criteria should be enumerated. Reasons for exclusions should be tracked. For those declining enrollment, the reasons should be specified and tracked. For eligible subjects agreeing to participate, the consenting process should be transparent and documented, and consent obtained by study personnel with no or minimal perceived conflicts of interest. The care providers for subjects who consent to participate should be notified and informed of procedures for reporting adverse effects and concomitant conditions and treatments.

Retention

The success of a study is dependent on the number of subjects who complete participation and have measurement of study outcomes. For various reasons, which must be tracked and documented, subjects will either terminate their further participation (dropouts) or will be lost and unable to be contacted (loss to follow-up). In planning for recruitment, extra subjects above those specified by the sample size calculations should be recruited in order to account for an estimated proportion of dropouts and loss to follow-up and to maintain study power. If dropout and loss to follow-up occur differently in the study groups being compared, this can unbalance

the groups both regarding numbers and characteristics, which can then introduce bias. Dropouts can occur when subjects decline to return for study visits, change eligibility, develop adverse effects, no longer require ongoing treatment, change their accessibility, or simply decide to withdraw from further participation. Loss to follow-up occurs when the subject can no longer be contacted, which may represent an intentional subject withdrawal or may be due to death, relocation, or unreported changes in contact information.

Strategies to maximize retention and completion should be considered in the study design phase and incorporated into trial operations. Dropouts can be minimized by keeping participation short and simple and minimizing inconveniences, establishing supportive relationships with study personnel and addressing all concerns, creating an appealing and organized environment for study visits and measurements, covering any participation-related costs, and providing feedback where possible. Loss to follow-up can be minimized by collecting as much contact information as feasible at the time of recruitment, including alternative means of contact and contact information of family or friends and care providers. Additional sources of information can be used to trace lost subjects with whom direct contact has been lost.

Crossover and Compliance

Sometime subjects may not receive or be compliant with the assigned study intervention. Crossovers occur when a subject randomized and assigned to a study intervention either receives nothing or receives the alternative or comparison intervention, and vice versa. In essence, the subject is changing study groups. Crossovers can occur during the initial application of the intervention, when criteria are unexpectedly noted that preclude or contraindicate that intervention. It occurs when the subject experiences adverse effects and discontinues treatment or pursues alternative treatment, and when the clinical condition changes such that the study intervention is no longer applicable or continued treatment is unethical. Crossover does not preclude ongoing participation in the study and completion of study measurements and outcomes assessments, as these subjects do not necessarily drop out. However, they do complicate comparison of study groups. The convention is to analyze crossovers according to their original assignment, referred to as an intention to treat analysis. This has the potential to minimize observed effect size, but it maintains freedom from allocation bias achieved by randomization. Alternatively, statistical adjustments can be made to minimize confounding.

Compliance with study interventions can also minimize the observed effect size. This includes subject compliance and discontinuations that may be as a result of discretion of the treating care providers. Strategies to monitor compliance, such as overdispensing and then counting returned medication, compliance logs, or devices that record when medication is accessed, or indicative testing of blood levels or treatment effect should be incorporated into study procedures. Compliance should be tracked, and the reasons for noncompliance recorded, as well as action taken. Frequent reminders and feedback regarding compliance can be useful. Episodes of both temporary and permanent discontinuation of study interventions should be minimized and prevented by frequent contact with both subjects and treating care providers. Decisions regarding discontinuations should be discussed with study personnel. Discontinuations should be tracked and reasons documented. Again, the convention in analysis is to analyze subjects according to initial study assignment, or by intention to treat. Additional analyses are often performed to compare groups according to intervention actually received,

or with adjustments for compliance and discontinuations. These analyses should be viewed as secondary, since biases may be introduced, but they can be supportive of results from the primary intention to treat analysis.

Quality Control

Quality control is an important aspect of clinical trial execution, putting place methods for standardizing and monitoring the implementation of a trial in an effort to preserve the study's internal validity. Careful quality control can help to avoid incidences of inaccurate or imprecise data collection, missing data, or data falsification, all of which are likely to introduce error in the study results and undermine the strength of any conclusions drawn. The larger a clinical trial, the greater the importance of quality control—increasing numbers of investigators and primary sites of data collection introduce mounting opportunity for error and inconsistency in study implementation.

Standardization is one of the primary means of implementing quality control in clinical trials. Standardization measures are often implemented before the start of a study, and function to minimize variation in and absence of data through the systematization of study methods and practices. Study aspects often standardized include measurement procedures, working lab and clinical definitions, and data collection, storage, and analysis protocols. The most fundamental tool available for the standardization of a clinical trial is the operations manual, essentially an expanded protocol precisely detailing important methods to be used in implementing the study (Table 78.16). The operations manual is meant to be readily available to all study personnel for the entire duration of the study, and consulted when any protocol uncertainties arise. Training and certifying all study personnel in proficiency for all study procedures is also a useful means of implementing standardization. Training and certification helps to reduce the inter- and intraobserver variability in any study measurements, as well as ensure clear understanding of all study protocols and definitions for all study personnel. Regular performance reviews of study personnel and whole trial centers help to maintain standardization measures throughout the duration of the trial, by auditing data collection and evaluating adherence to protocol as outlined in the operations manual. Such reviews are especially important in longer-term trials, where it may be difficult to maintain the rigor of standardization methods long after the study has begun.

Adjudication is an especially important quality control measure where considerable variability may exist between investigators with respect to the ascertainment and reporting of events (Table 78.18). Particularly with outcomes requiring a complex and/or subjective judgment, adjudication plays a key role in confirming the reproducibility and reliability of any study findings. Several methods exist for standardizing

and controlling the adjudication process. Quality control by repeated adjudication involves the replication of a given outcome measurement or diagnosis by multiple observers, and comparison of the individual results to assess the interobserver reliability. The implications of repeated adjudication vary depending on the type of outcome being ascertained. For nonnumerical outcomes, such as attribution of cause of death, comparison of multiple judgments helps assess the interobserver reliability of the measure and the most likely correct outcome. A high degree of disagreement between observers may indicate a high level of error and/or bias in the adjudication process, and require that the outcome be subject to further assessment before a final decision is made. In the adjudication of a numerical outcome, multiple measurements can be averaged to reduce the variation in the reading.

Central adjudication committees or core labs are a robust method of quality control in the adjudication process. A core lab is a centralized data collection and interpretation system, which acts to ensure that standardization is strictly maintained throughout the processes of outcome adjudication, reporting, and analysis. Core labs may take one of two forms in clinical trials: that of a physical laboratory site centralizing all lab-dependent data analysis, or that of an auxiliary review center charged with verifying outcomes adjudicated and reported by individual trial centers (Table 78.19). Both types of core labs are able to guarantee a high degree of standardization of the adjudication process, since only a small number of individuals are responsible for either all study adjudication, or the verification of each reported outcome within a strict set of criteria. Although more costly, time and labor-intensive than repeated adjudication, core labs are a preferred method of standardization in clinical trials, especially those involving multiple separate study centers.

Data and Safety Monitoring

Data monitoring describes the process of screening and analyzing data as they accumulate over the course of a trial. It is primarily a method of quality control, serving to detect and correct important discrepancies such as absent, imprecise, or falsified data. Such discrepancies may be inevitable, due to forces such as patient noncooperation and error introduced by trial staff or equipment. By allowing preliminary results analysis of incoming data, data monitoring also plays a role in aspects of study planning and administration, such as verification and adaptation of the study's working hypothesis and assessment of possible safety issues (Table 78.20).

Quality control of the data collection process can involve multiple strategies of data monitoring. Some may be performed by study personnel concurrent to data collection and database entry, such as minimization of the lag time between data collection and database entry, manual data checks, and double data entry. Other monitoring procedures may be initiated before a block of data collection has begun, or carried out on working databases after data entry is complete. Such methods include duplicate analysis testing of the data collection process, or software checks for absent, incorrect, or falsified fields in a working database (Table 78.21).

Data editing is the process of correcting errors or absences in data as detected by data monitoring. In order to avoid undermining the integrity of the data collection process, any data editing procedures must be standardized in the operations manual before the start of the study, and clearly documented when performed.

Trial monitoring for safety and efficacy should be conducted by allowing preliminary or interim analyses of subject characteristics and safety and efficacy outcomes to be performed as data are being collected. Such analyses may help

TABLE 78.18

Sources of Intra- and Interobserver Variability in Outcome Adjudication

- Multiple, complex or subjective decisions involved in the adjudication process
- Large numbers of possible decision results
- Lack of attention to decision-making protocols in the adjudication process
- Errors or omissions in available data

TABLE 78.19 Alternate Forms of Core Labs in Standardization

Type of Core Lab	Description	Role in Standardization
Centralized laboratory	Physical, standardized lab site.	Allows all adjudication to be performed by a handful of individuals under highly standardized conditions.
	Staffed by a small number of highly trained, fully blinded technicians.	Drastically reduces intra- and interobserver variability in outcome reporting.
	Receives collected data from separate trial center(s), is responsible for final adjudication and analysis of all outcomes.	
Quality Assurance (QA) Center	Supporting trial review center.	Allows a small number of individuals to verify all reported outcomes, based on highly standardized criteria.
	Staffed by a panel of expert reviewers.	
	Responsible for verifying outcomes adjudicated and reported by individual trial centers, by ensuring each decision meets a specific set of protocol-specified criteria.	Ensures final outcome results are unaffected by variability in adjudication at individual study centers.
	May also fill other roles in quality control, such as organizing and monitoring adjudication procedures, undertaking performance reviews, and coordinating training and certification of study center staff.	
	Most often employed in multicenter trials.	

to detect emerging data trends and relationships, allowing formulation and adaptation of working hypotheses and adjustments to sample size as the trial progresses. Interim analyses should be specified in advance and lead to adjustment in initial sample size estimation.

An *independent DSMB* should be formed, and should assume responsibility for ensuring compliance with the study protocol and procedures, monitor recruitment and study timelines, assure quality control, and to review any interim analysis performed as part of data monitoring. The activities of the DSMB should be carried out independently from the investigators of a study, to avoid any conflict of interest that may arise in determining and reporting significant interim results. Having interim analyses performed and reviewed by an independent body also carries the benefit of maintaining any investigator blindness in a trial, since results analysis and review may require knowledge of treatment assignments. Bodies responsible for performing this analysis may be a preappointed, independent review committee, or simply the institutional review board of a single-center study.

The decision to prematurely stop a study before completion is informed by data monitoring and interim analyses, which may identify exceptional information that may warrant stopping a study, such as clear excessive benefit or harm related to the study intervention (Table 78.22). The decision to prematurely stop a study in response to interim results is a critical one, with serious repercussions if miscalculated. For example, failing to stop a study under necessitating circumstances can have severe ethical implications, by either exposing subjects to unacceptable harm or preventing public access to an excessively beneficial treatment. Conversely, unnecessarily stopping a study can be very costly in terms of wasted resources, and may invalidate any useful results emerging before the study was stopped. Therefore, careful consideration and weighing of all possible risks and benefits must be done by qualified individuals before the decision to prematurely stop a study is made (Table 78.23). Ideally, thresholds of benefit or risk should be prespecified in advance of any interim analysis, preferably in the design or operationalization stages of trial development. These thresholds should be of greater magnitude

TABLE 78.20 Purposes of Data Monitoring

Quality Control of Data Collection

- i. Detection of missing data from final database.
- ii. Discovery and correction of inaccurate or imprecise data.
- iii. Prevention of falsification of data.

Administrative and Planning Purposes

- Performance of preliminary analyses, for:
- i. Generation or modification of working hypotheses.
 - ii. Assessment of safety.
 - iii. Assessment of excessive risks or benefits that may warrant early stopping of the trial.

TABLE 78.21 Strategies of Data Monitoring

Strategy	Timing of Implementation	Description	Purpose
Timely data entry	Concurrent with data collection and entry	Minimization of lag time between data collection and entry into database.	Minimizes data entry errors, since data are fresh, still have clear context. Allows efficient completion of any missing or incorrect fields, since data source was recently available.
Manual data checks	Concurrent with data collection and entry	Staff review of data for obvious errors before and after entry into database.	Allows efficient verification of overall accuracy and completeness of data. Minimizes data entry errors.
Double data entry	Concurrent with data collection and entry	Independent entry of data by two separate individuals, comparison of the resulting databases for discrepancies.	Minimizes data entry errors. Verifies the overall accuracy data entry.
Duplicate analysis	Before data collection begins	Intermittent study processing of known, blinded standards alongside patient samples.	Provides quality control information on the data collection and entry processes.
Software checks	After data entry is completed	Computerized queries to detect missing or unreasonable values in a working database.	Allows detection and correction of data discrepancies after database entry is complete.

than the effect sizes hypothesized for primary and secondary outcomes, and when statistical testing is applied to determine the level of confidence in the observed effect, a more rigorous (i.e., smaller) p -value should be specified.

ANALYSIS ISSUES FOR CLINICAL TRIALS

Data analysis is the process whereby the data collected are used to test the study hypotheses and to answer the study questions. Hence, a data analysis plan must not just be a specification of

statistical tests to be applied, but a description of the means by which results are described and associations determined, with the primary association of interest in a clinical trial being that of the study interventions with the primary and secondary outcomes. The data analysis should also detail plans for further specifying these associations, either by adjustment or subgroup analyses to determine the effects of confounding and interaction. Clinical trials datasets also provide excellent observational data for exploring associations and hypothesis generation, other than with the study interventions. These analyses should also be planned and specified. The analysis plan together with the nature and distribution of variables being used are the determinants of the statistical methods to be applied. The data analysis plan is a key component that should be clearly specified in the design phase of the clinical trial, although modifications may be required when data analysis actually proceeds. These modifications should be justified and documented.

TABLE 78.22 Exceptional Circumstances Warranting Stopping a Study

Serious Adverse Risk of Treatment	Excessive Benefit of Treatment
<ul style="list-style-type: none"> ■ Preliminary analysis demonstrates that treatment poses a serious risk of adverse side effects to patients. ■ Unethical to continue to administer study—all patients should be withdrawn from active treatment. ■ Treatment should not be administered further to new subjects. 	<ul style="list-style-type: none"> ■ Preliminary analysis demonstrates a clear and excessive benefit associated with the experimental treatment. ■ Unethical to withhold an excessively beneficial—study should be stopped to expedite availability of treatment to public.

Data Management, Cleaning, and Descriptive Statistics

Investigators frequently underestimate the amount of effort required to prepare a dataset for analysis. However, the

TABLE 78.23 Factors to be Considered in the Decision to Stop a Study

- Reliability of the interim results in question.
- Follow-up period required for adequate assessment of the effects of the intervention.
- Relative weight of risks and benefits of the intervention to subjects, future patients.

quality control and data-monitoring procedures described previously and implemented during the study execution should minimize many data problems. The first step in the preparation of a dataset for analysis is to ensure completion of all data entry. Quality checks should be in place. Descriptive statistics including frequencies and distributions are then performed for every variable. The number and proportion of missing values should be determined, and efforts made to determine those values. Each variable should be examined for values that are out of range, with verification if they represent true outlier values or are data errors. In addition, values that are miscoded should be corrected. Care should be taken for verifying conditional variables, which are variables the values for which are linked to another variable. For example, duration of circulatory arrest should not have a value if the subject did not have a period of circulatory arrest. The process of data cleaning and verification, and the determination of descriptive statistics should generate a high degree of familiarity with the quantity, quality, and limitations of the available data in order to inform performance of the data analysis plan.

Test of Randomization

While randomization should minimize unbalancing regarding subject characteristics, it does not guarantee that random or systematic differences that may be influential in a comparison of outcomes are not present. Unbalancing, or incomplete randomization, may be a chance occurrence or represent flaws or deviations in the randomization procedure and assignment. One can test the randomization procedures that were employed to verify the randomness and to ensure that the system does not have any inherent bias or predictability. One can also audit the randomization procedures and their implementation, looking for documentation of deviations and their reason.

A *comparison of baseline characteristics* between study groups, the first comparison in the analysis of a clinical trial, and usually the first table in a published report, is a test of the randomization. It should be recognized that one can only detect unbalancing of characteristics that were measured. However, effective randomization should minimize unbalancing for both measured and unmeasured characteristics. The frequencies or distribution of values for each variable within each group should be calculated and compared. Statistical testing can be applied, which can identify those differences that represent deviations from balancing that may not be attributable to chance occurrence. However, one should give more relevance to the magnitude of actual differences than to p -values. Usually, one is comparing across many baseline characteristics, and hence some p -values will meet the threshold for statistical significance on the basis of chance alone as a result of multiple comparisons. Thus, the presence of some unbalancing does not necessarily point to a flaw in randomization procedures. In addition, p -values are highly dependent on the number of subjects and the variation in distribution, in addition to the magnitude of differences. If there is a large number of subjects, small differences have a high likelihood of achieving a significant p -value, yet not be relevant indicators of bias. If there is a small number of subjects, large differences may not be statistically significant, yet impart bias in the comparison of outcomes. One should also look for patterns among the differences in characteristics, particularly among characteristics that may be associated with one another, which may further indicate important unbalancing.

Statistical adjustment for unbalancing can be applied during comparisons of outcomes. This should be performed after the unadjusted intention-to-treat analysis. One can use multivari-

able regression techniques to adjust for baseline characteristics that were significantly different, either statistically or by magnitude, as noted during the test of randomization. This adjustment can be more formally performed by calculation and adjustment or matching for propensity score. A propensity score represents the probability or propensity that a given subject, based on their measured baseline characteristics, was randomized to a particular study intervention group, and can provide simultaneous adjustment for multiple characteristics. The propensity score is calculated from a multivariable logistic regression model with assignment as the dichotomous dependent variable, and relevant baseline characteristics as independent variables. The ensuing regression equation can be solved for individual subjects to give the probability of assignment. The propensity score can then be used either as an adjustment variable when comparing outcomes, or subjects can be matched between groups regarding propensity score, and matched pair analyses applied.

Outcomes Comparisons

The foremost comparison of outcomes between study groups should be an unadjusted comparison based on an intention-to-treat analysis. Intention-to-treat analysis preserves the random allocation that minimizes bias. Subjects are analyzed according to the original group allocation, regardless of crossover, coin-tervention, dropout, noncompliance or other deviations from the study protocol. This is the most valid type of analysis, although if deviations are great, it can minimize the observed effect size.

Statistical testing is applied to comparisons in order to determine the chance probability of observing the magnitude of difference between groups if the null hypothesis is actually true and there indeed is no true difference. This probably is the p -value, and by convention one usually sets the level of statistical significance at a $p < 0.05$, meaning that there is a <5% chance that the observed difference is a random error. The type of statistical test employed to determine the p -value depends on the number of groups and the nature and distribution of the outcome variable.

Measures of effect of study interventions are important for expressing the magnitude of effect and in interpreting its relevance or importance. Of primary interest is the absolute effect, or the direction and magnitude of the difference in the outcome between study groups. One usually calculates this as the effect in the study intervention group minus the effect in the comparison group. Of secondary interest is the relative effect. One usually calculates this as the absolute effect divided by the effect in the comparison group, expressed as a percentage. One applies statistical testing and calculates confidence intervals around the absolute effect, which then inform the interpretation of the observed effect. One can also calculate power, or the probability of correctly rejecting the null hypothesis (no effect) and avoiding a type II error. Power is of more importance when the results of the study are inconclusive based on confidence, or when there are important differences in the magnitude, and sometimes direction as well, of the observed effect versus the hypothesized effect. Table 78.24 outlines a worked example of clinical trial results based on the trial previously described in Table 78.15.

Confidence intervals are similar in nature to p -values, but much more informative. Based on the observed effect and its variation, and influenced by the number of subjects studied, a confidence interval is the range of possible effect sizes over which one can be reasonably (usually 95%) confident that true effect lies. Confidence intervals that include

TABLE 78.24 Worked Example of Effect Measures and Interpretation

Scenario: The clinical trial of thromboprophylaxis in patients after Fontan procedure outlined in Table 78.15 is performed. However, due to slow recruitment and lack of funding, the trial is prematurely stopped short of the intended sample size of 112 subjects per group, with 111 total subjects randomized, 57 to ASA, and 54 to warfarin. At 2 years after randomization, an intention-to-treat analysis of Kaplan-Meier estimates of the primary outcome of thrombosis or thrombosis-related event showed a period prevalence of 14% for the ASA group (8/57) and 24% for the warfarin group (13/54).

Absolute effect: $0.24 - 0.14 = +0.10$. For every 100 patients treated with warfarin, 10 additional patients would have thrombosis/event over the number who would have had thrombosis/event had they been treated with ASA (baseline or comparison risk).

Relative effect: $(0.24 - 0.14)/0.14 = +0.71$. Warfarin is associated with a 71% relative increase in thrombosis/events over treatment with ASA.

p-value: 0.18. There is an 18% probability (two-tailed) of observing an absolute of effect of +0.10 by chance if the truth is that there is no effect.

95% confidence interval around the observed absolute effect: -0.06 to $+0.24$. The confidence interval includes 0, meaning that one can be 95% sure that the truth may reasonably be no effect. If one assumes that an absolute reduction in thrombosis/events of -0.15 over ASA would be the minimal clinically important effect to justify preference for warfarin, then the lower limit of the confidence interval of -0.06 excludes this effect, meaning that one can be 95% sure that a clinically important benefit of warfarin does not in truth exist. If one also assumes that an absolute increase in thrombosis/events of 0.15 associated with warfarin compared to ASA would be the minimal clinically important harm to justify a recommendation not to use warfarin, then the upper limit of the confidence interval of $+0.24$ includes this effect, meaning that one can be 95% sure that a clinically important harm does in truth exist.

Power: 0.20. Based on the observed findings and the number of subjects studied, there is only 20% chance of correctly rejecting the null hypothesis or avoiding a type II error, that is, concluding that there is no differential effect of warfarin compared to ASA when in truth there is no effect.

Interpretation: One can be confident that there is no clinically important reduction in thrombosis/events with warfarin thromboprophylaxis over ASA. However, one cannot be confident that there is in truth no difference, and in fact, one can be reasonably confident that warfarin is in truth associated with a clinically important increase over ASA in the risk of thrombosis/events. However, the study did not include a nontreatment group, so one cannot be certain that warfarin is not of benefit, just that it appears to be of less benefit compared to ASA. The results must be viewed in light of some limitations, including a high and disproportionate prevalence of crossovers, dropouts, out of therapeutic target range and study drug discontinuations, a high prevalence of deviations from the study protocol, as well as the limited power reflective of the lower than expected number of enrolled and randomized subjects.

Of note: The analysis depicted was matched exactly to the analysis as specified in the sample size calculations. However, for the reported trial, given the number of dropouts and, hence, censored observations and the late performance of protocol transesophageal echocardiography beyond the 2-year study endpoint, log rank testing was performed on the entire stratified Kaplan-Meier curve, with no significant difference noted (p -value 0.45). There was also a convergence after 2 years of the incidence of thrombosis/events between groups. The hazard ratio for outcome for warfarin versus ASA was 1.35, indicating a 1.35 times greater risk of outcome with warfarin. The 95% confidence interval was 0.62 to 3.00, which includes a hazard ratio of 1 (no difference, but includes an upper limit of 3.00, or a three times greater risk of outcome with warfarin versus ASA. This risk would probably be deemed above a minimum clinically important threshold for harm.

an effect size indicative of no difference lead one to conclude that one cannot be confident that the observed effect size is not a random error and that the null hypothesis cannot be rejected. If that same confidence interval also includes an effect size that would meet minimal thresholds for a clinically relevant benefit or harm, then the study results are inconclusive, with a relevant effect size being neither confidently proven nor disproven. This scenario occurs most frequently when observed effects sizes are less than what was hypothesized or variation was greater, or the number of subjects studied is insufficient to give the needed power to detect or be confident that the observed effect represents the truth. Ideally, one wishes to have a confidence interval around the observed effect size that excludes no difference and for which the lower limit is not below the minimal threshold of clinical importance.

Deviations from intention-to-treat analysis of outcomes can be of importance when the results of the intention-to-treat analysis are inconclusive or differ significantly from what was

hypothesized. These deviations may introduce bias, since they sometimes depart from randomized assignment, but may be more clinically meaningful. The most common deviation is to perform comparisons based on intervention actually received. This type of analysis may be more meaningful if there are a lot of crossovers. Another deviation is to incorporate measures of compliance with study interventions into the analysis, or to analyze only outcomes occurring before any study intervention discontinuation or dropout. Adjustment, matching, and propensity scores can be used in analyses to statistically adjust for any potential bias in random allocation, or to minimize potential bias from important confounders. Analysis can be conducted to look for differential effect within prespecified subgroups of subjects, or to look for characteristics that interact with the study interventions in their effect on outcomes. The results of these types of analyses are given less weight, and are usually viewed as exploratory or hypothesis generating. Nonetheless, they enrich the information derived from a clinical trial.

REPORTING AND APPRAISAL ISSUES FOR CLINICAL TRIALS

Since clinical trials have a well-defined and structured methodology, usually flaws and deviations are readily apparent. However, consideration of those flaws and deviations, which represent potential bias, is only possible if all aspects of the design and execution of the trial are completely disclosed and the results are presented in sufficient detail, together with a balanced interpretation that includes discussion of the study limitations and the generalizability of the findings. Clinical trials are given the highest weight in systematic reviews and clinical practice guidelines, and are the sole contributors to the majority of meta-analyses. This is predicated on the fact that clinical trials provide the highest quality of evidence based on having the greatest possibility of absence or minimization of bias. The usefulness of a clinical trial report is dependent on the degree to which the study and results can be critically appraised, which is dependent on complete reporting and transparency.

The *CONSORT Group* (Consolidated Standard of Reporting Trials; www.consort-statement.org) is a group of international clinical trials experts, statisticians, journal editors, and authorities from industry, as well as some members from the Cochrane Collaboration (www.cochrane.org). The Group has defined guidelines for standardized reporting of clinical trials, which have been adopted as a reporting requirement by most of the leading medical journals. The CONSORT Flow Diagram (Fig. 78.2) shows how the tracking of subjects

from enrollment, through allocation, follow-up, and analysis should be depicted, together with reasons for any deviations. This figure should be the first figure in any report of a clinical trial. The CONSORT Group also provides a CONSORT Statement consisting of a 25-item checklist (Fig. 78.3), together with an explanation and elaboration document to be used in conjunction with the checklist. Many journals now require that the completed checklist be submitted together with the manuscript draft.

Transparency in clinical trial reporting is also achieved by ensuring that the trial was registered prior to the start of any subject recruitment. The name of the trial registry, the date of registration and the registration number should be reported. The report must also include details regarding institutional research ethics board review and approval, and the process for obtaining consent for participation and how it was tracked. The report may detail how compliance with privacy policies was ensured and maintained. All sources of funding and other support must be disclosed, as well as any other potential conflicts of interest on the part of investigators and authors, such as stock ownership or financial interest, consultancy, and honoraria. Provisions should be specified for making the full protocol for the clinical trial available. Assurances must be provided that all authors had full access to the study data and had taken full responsibility for the reported results, had participated sufficiently in the generation of the trial report or manuscript, and approve of any version and its disposition.

Critical appraisal of reports of clinical trials is made easier when the information specified in the CONSORT Statement checklist is clearly provided. Critical appraisal is usually aimed

Figure 78.2. CONSORT flow diagram for reporting of subject accrual and retention.

CONSORT 2010 checklist of information to include when reporting a randomised trial*

Section/Topic	Item No	Checklist item	Reported on page No
Title and abstract			
	1a	Identification as a randomised trial in the title	_____
	1b	Structured summary of trial design, methods, results, and conclusions (for specific guidance see CONSORT for abstracts)	_____
Introduction			
Background and objectives	2a	Scientific background and explanation of rationale	_____
	2b	Specific objectives or hypotheses	_____
Methods			
Trial design	3a	Description of trial design (such as parallel, factorial) including allocation ratio	_____
	3b	Important changes to methods after trial commencement (such as eligibility criteria), with reasons	_____
Participants	4a	Eligibility criteria for participants	_____
	4b	Settings and locations where the data were collected	_____
Interventions	5	The interventions for each group with sufficient details to allow replication, including how and when they were actually administered	_____
Outcomes	6a	Completely defined pre-specified primary and secondary outcome measures, including how and when they were assessed	_____
	6b	Any changes to trial outcomes after the trial commenced, with reasons	_____
Sample size	7a	How sample size was determined	_____
	7b	When applicable, explanation of any interim analyses and stopping guidelines	_____
Randomisation:			
Sequence generation	8a	Method used to generate the random allocation sequence	_____
	8b	Type of randomisation; details of any restriction (such as blocking and block size)	_____
Allocation concealment mechanism	9	Mechanism used to implement the random allocation sequence (such as sequentially numbered containers), describing any steps taken to conceal the sequence until interventions were assigned	_____
Implementation	10	Who generated the random allocation sequence, who enrolled participants, and who assigned participants to interventions	_____
Blinding	11a	If done, who was blinded after assignment to interventions (for example, participants, care providers, those	_____

Figure 78.3. CONSORT checklist for reporting of clinical trials. (*Continued*)

		assessing outcomes) and how	
	11b	If relevant, description of the similarity of interventions	
Statistical methods	12a	Statistical methods used to compare groups for primary and secondary outcomes	
	12b	Methods for additional analyses, such as subgroup analyses and adjusted analyses	
Results			
Participant flow (a diagram is strongly recommended)	13a	For each group, the numbers of participants who were randomly assigned, received intended treatment, and were analysed for the primary outcome	
	13b	For each group, losses and exclusions after randomisation, together with reasons	
Recruitment	14a	Dates defining the periods of recruitment and follow-up	
	14b	Why the trial ended or was stopped	
Baseline data	15	A table showing baseline demographic and clinical characteristics for each group	
Numbers analysed	16	For each group, number of participants (denominator) included in each analysis and whether the analysis was by original assigned groups	
Outcomes and estimation	17a	For each primary and secondary outcome, results for each group, and the estimated effect size and its precision (such as 95% confidence interval)	
	17b	For binary outcomes, presentation of both absolute and relative effect sizes is recommended	
Ancillary analyses	18	Results of any other analyses performed, including subgroup analyses and adjusted analyses, distinguishing pre-specified from exploratory	
Harms	19	All important harms or unintended effects in each group (for specific guidance see CONSORT for harms)	
Discussion			
Limitations	20	Trial limitations, addressing sources of potential bias, imprecision, and, if relevant, multiplicity of analyses	
Generalisability	21	Generalisability (external validity, applicability) of the trial findings	
Interpretation	22	Interpretation consistent with results, balancing benefits and harms, and considering other relevant evidence	
Other information			
Registration	23	Registration number and name of trial registry	
Protocol	24	Where the full trial protocol can be accessed, if available	
Funding	25	Sources of funding and other support (such as supply of drugs), role of funders	

*We strongly recommend reading this statement in conjunction with the CONSORT 2010 Explanation and Elaboration for important clarifications on all the items. If relevant, we also recommend reading CONSORT extensions for cluster randomised trials, non-inferiority and equivalence trials, non-pharmacological treatments, herbal interventions, and pragmatic trials. Additional extensions are forthcoming: for those and for up to date references relevant to this checklist, see www.consort-statement.org.

Figure 78.3. (Continued)

TABLE 78.25 Critical Appraisal of Clinical Trials

1. Is the study well designed and executed such that the results are likely to be free of bias, and therefore representative of the truth?
 - a. Was treatment assignment randomized? If so,
 - i. is the randomization strategy specified?
 - ii. was it tamper-proof?
 - iii. was it successful, in that baseline characteristics are comparable between comparison groups?
 - b. Are all of the study subjects accounted for throughout the study, and analyzed according to their initial assignment?
 - c. Were the groups treated equally in all other respects besides the study maneuver?
 - d. Are the primary and secondary outcomes relevant and sufficient?
 - e. Was the study period sufficiently long for the outcomes to occur?
 - f. Was the study maneuver, assessments, and data analysis blinded to the initial assignment?
 - g. Is there a stated hypothesis, and are sample size calculations provided?
2. What are the results, and is the analysis and presentation in a format that allows assessment of the magnitude and reliability of treatment effects?
 - a. What are the magnitudes of the treatment effects?
 - i. Absolute effects
 - ii. Relative effects
 - b. How reliable are the estimates of the treatment effects?
 - i. Are standard errors or confidence intervals provided?
 - ii. Are power calculations provided for nonsignificant differences?
3. Are the results relevant and applicable to the clinical scenario at hand?
 - a. Are inclusion and exclusion criteria described in sufficient detail?
 - b. Is the treatment described in sufficient detail to enable implementation?
 - i. Is the treatment feasible in the clinical scenario?
 - c. Is any information provided that would allow further specification of the treatment effects to the characteristics of an individual patient?
 - i. What are the benefits and harms for the specific patient?
 - d. What are the values and preferences for the specific patient?

at determining the strength of the evidence that a specific study provides, and whether the findings are relevant to a meta-analysis, clinical guideline, or to one's own clinical practice. Key questions for appraisal are outlined in Table 78.25. Appraisal of a trial begins with an assessment of the validity of the trial, primarily through appraisal of the study design and execution. The next step is an assessment of the results, their statistical and clinical significance, and their reliability. The balance of benefits versus risks should be evident and considered. The final step is an assessment as to the applicability of the study findings to the clinical scenario at hand. Further information and resources regarding critical appraisal and the practice of evidence-based medicine can be found through The Journal of the American Medical Association (www.jamaevidence.com), which had previously published some of the first User's Guides to critical appraisal of the medical literature (11,12).

The standard of clinical care is not solely determined by the results of a single clinical trial, but a well-designed and executed clinical trial with clinically important results can influence the

standard of care. Further criteria to consider are outlined in Table 78.26.

ACKNOWLEDGMENTS

The chapter author would like to acknowledge the outstanding and invaluable contributions of Elizabeth Niedra in the preparation of this chapter.

RECOMMENDED RESOURCES

This chapter provides an overview of the value, design, execution, analysis, reporting, and appraisal of clinical trials. For more detailed information, a list of excellent textbooks is provided. Additional resources can increasingly be found online.

TABLE 78.26 Criteria to Consider Before Adopting a New Intervention as the Standard of Care

- There is a sound rationale for the therapy based on current knowledge of physiology and pathophysiology in the specific population to which the therapy is to be applied.
- It is feasible for the therapy to be more widely applied in the clinical setting.
- The best quality evidence exists that the therapy has a beneficial effect on the primary outcomes of interest.
- The full spectrum of beneficial and adverse effects of the therapy is known.
- Factors that influence the effects of the therapy in the clinical setting have been identified.
- The best quality evidence exists that the therapy compares favorably to currently applied therapies.
- Patients' preferences for the therapy are favorable. The therapy can be applied in a cost-effective and efficient manner in the clinical setting. The practical limitations for widespread delivery of the therapy are minimal.

Michael Artman ■ Gregory L. Kearns

The use of drugs for patient treatment carries a single therapeutic imperative, namely, selecting the best drug and administering it in a dosing regimen that is predictive of efficacy and safety. While a “one size fits all” approach to drug dosing in adults is the norm, pediatrics represents the exception whereby development requires that drug dosing be individualized. A safe, therapeutic drug regimen for children must account for the impact of ontogeny and other factors that contribute to variability in the exposure–response relationship.

Human development represents a continuum of biologic events that includes somatic growth, neurobehavioral development, and eventual reproduction. During the process of maturation over the first 15 years of life, profound physiologic changes occur in a variety of processes that can alter both drug disposition and action (1). Moreover, during the first 2 years of life, many of these changes are dynamic and their association with body size can be nonlinear—a situation that precludes the use of fixed (i.e., age-independent) drug dosing regimens and, in some instances, the application of simple allometric scaling to predict age-appropriate drug dose. Therefore, safe and effective drug therapy for children requires a fundamental and integrative understanding of how ontogeny contributes to the other factors (e.g., genetic constitution, the role of environment, the impact of concomitant disease and its treatment) capable of influencing both drug disposition and action and thereby, the relationship between drug dose, concentration, effect, and efficacy. Such considerations collectively represent the essence of pediatric clinical pharmacology. A sound understanding of basic pharmacology principles is necessary for facilitating individualization of drug treatment in infants, children, and adolescents.

Over the past 30 years, pediatric clinical pharmacology has evolved from an area of research emphasis/focus within pediatrics to a subdiscipline of clinical pharmacology with demonstrated therapeutic importance to the medical care of pediatric patients. The large amount of knowledge generated in the field of pediatric clinical pharmacology during this time precludes the presentation of a comprehensive, content-based review or treatise in this chapter. Rather, it is our intention to provide the reader with a “primer” on pediatric clinical pharmacology and, in particular, its relationship to the practice of pediatric cardiology through a presentation of fundamental principles and their illustration using relevant therapeutic examples. We also present summary information pertaining to the clinical pharmacology of drugs commonly used in pediatric cardiology. Collectively, this will equip the reader with a solid foundation for further inquiry and also provide a fundamental, conceptual framework upon which sound therapeutic decision making in pediatric cardiology can be based.

COMMON DEFINITIONS OF TERMS IN CLINICAL PHARMACOLOGY

As is the case with many disciplines, clinical pharmacology has its own lexicon, an understanding of which is fundamental to the clinical application of its principles to therapeutic decision making. The following paragraphs represent a glossary of common terms in clinical pharmacology, each of which is accompanied by a conceptual summary derived from information contained in a recent textbook (2).

Absolute bioavailability (F) is the fraction of a drug dose administered by an extravascular route that is absorbed into the systemic circulation. It is determined within a given individual by comparing the area under the plasma concentration with time curve (area under the curve; AUC) following an oral dose of the drug to that resulting from an intravenous dose (where bioavailability is generally 100% given that no absorption occurs).

Relative bioavailability is similarly determined by comparing the AUC following extravascular administration of a “test” formulation and a “reference” drug formulation (e.g., comparing the AUC from an extemporaneously formulated liquid to that from a marketed oral solid dosage form of a given drug).

Absorption of drugs describes the process of drug uptake from a site of extravascular administration (e.g., oral, intramuscular, subcutaneous, intraperitoneal, intraosseous, and intratracheal) into the systemic circulation. The majority of drug absorption occurs via passive diffusion, although for some compounds, carrier-mediated and/or active transport (e.g., via a transporter such as P-glycoprotein) can occur. Because a drug must generally exist in a true solution to be absorbed, liberation of the active drug from a drug product (e.g., release of a calcium channel blocker from a sustained-release dose formulation) can be a rate-limiting event for absorption. Drug absorption is most accurately conceptualized by considering both rate (e.g., absorption half-life, time to peak concentration) and extent (e.g., bioavailability), either of which can be influenced by biopharmaceutical (e.g., drug formulation), physicochemical (e.g., pH, solubility, hydro- and lipophilicity, protein binding, and complexation characteristics with food or drugs), and physiologic factors (e.g., barrier integrity, motility, volume and pH of body fluids at absorptive site, protein-binding capacity, and degradation/biotransformation potential).

Area under the curve (AUC) is a concentration- and time-dependent parameter that reflects systemic exposure to a drug. Mathematically, AUC represents the integral of blood levels of drug over time from zero to either a predetermined post-dose time point (i.e., $AUC_{0 \rightarrow t(x)}$) or extrapolated to infinity (i.e., $AUC_{0 \rightarrow \infty}$), which is done by using the apparent terminal elimination rate constant (similarly calculated from the observed plasma concentration vs. time plot) (Fig. 79.1).

Figure 79.1. Representative plasma concentration versus time curve. Illustrated are commonly referenced pharmacokinetic parameters including AUC, area under the curve; C_{\max} , maximal plasma drug concentration; k_e , the apparent first-order elimination rate constant; and T_{\max} , the time to achieve apparent peak plasma concentrations. (Reprinted from Abdel-Rahman SM and Kearns GL. The pharmacokinetic-pharmacodynamic interface: determinants of anti-infective drug action and efficacy in pediatrics. In: Feigin RD, Cherry JD, Demmler-Harrison GJ, et al., eds. *Feigin and Cherry's Textbook of Pediatric Infectious Disease*. 6th ed. Philadelphia, PA: Saunders-Elsevier, 2009:3158, with permission from Elsevier.)

Bioequivalence of a drug product reflects an assessment of whether one drug formulation (e.g., a generic drug) produces a rate and extent of absorption that is comparable to that of the reference formulation. It assumes that effect and toxicity profiles of the two drugs will be virtually identical if the systemic exposures (as determined from AUC) are comparable. The determination of bioequivalence as defined in current regulatory guidelines is purely pharmacokinetic in nature in that it does not involve a relative assessment of drug effect from a given drug product and/or dose.

Clearance (CL) of a drug is conceptually represented by the volume of blood from which a certain amount of unmetabolized drug is removed (i.e., cleared) per unit time by all pathways capable of drug removal (e.g., renal, hepatic, biliary, pulmonary). Clearance is generally represented as either total body (or plasma) clearance, renal clearance (CL_{ren}), or nonrenal clearance (CL_{nr}). The calculation of CL is made from knowledge of the AUC and for CL_{ren} , from knowing the total amount of drug excreted unchanged in the urine over a 24 or more hour period. For drugs administered by any extravascular route, CL yields an “apparent” value (e.g., CL/F) that must be corrected for the extent of absolute bioavailability. Finally, it should be noted that CL can be influenced by *ex vivo* procedures (e.g., extracorporeal membrane oxygenation, dialysis [hemodialysis, peritoneal dialysis, continuous hemofiltration with dialysis]).

Disposition refers to the collective processes of drug absorption, distribution, metabolism, and excretion/elimination, all of which occur simultaneously after drug administration as opposed to being discrete events. Pharmacokinetic behavior for a given drug is a common surrogate for disposition in that the concentration versus time profile for a given drug is determined by the aforementioned processes.

Elimination half-life ($T_{1/2}$) is defined as the time following drug absorption required for blood or plasma drug concentrations to be reduced by 50%. It is calculated from the apparent elimination rate constant (k_e), which is the slope of the apparent drug elimination phase from blood/plasma (Fig. 79.1). While $T_{1/2}$ is frequently considered as a “surrogate” for CL,

it should be noted that it is dependent both upon CL and the apparent volume of distribution. Practically, $T_{1/2}$ is an important pharmacokinetic parameter in that it can be used to predict when steady-state drug concentrations are attained (e.g., steady state reached at a time equal to four to five times the $T_{1/2}$ following the initiation of drug treatment or a change in dose/dosing regimen) or alternatively, when a drug should be eliminated from the body (e.g., 75% elimination in a period equal to three times $T_{1/2}$).

Peak concentration (C_{\max}) represents the highest concentration of drug attained in a particular biologic fluid following the administration of a drug dose. As illustrated in Figure 79.1, C_{\max} occurs at a corresponding postdose time (T_{\max}) that temporally reflects the time required for drug absorption following a dose administered by an extravascular route.

Pharmacodynamics of a drug reflects a relationship between drug exposure (i.e., concentration), time, and drug effect (both intensity and duration). Simply stated, pharmacodynamics is a reflection of what a given drug/dose does to the body and the association of the effect(s) with time of drug administration. In the context of clinical pharmacology, pharmacodynamics refers to the exposure–response (i.e., concentration–effect) relationship for a given drug.

Pharmacokinetics reflects a quantitative approach used to describe the movement of a drug throughout the body and also, concentrations (or amounts) of drug that reside in a given body space (e.g., fluid spaces and tissue). Pharmacokinetics is conceptualized by considering those characteristics that are the determinants of drug disposition.

Pharmacogenetics can be defined as the study or clinical testing of variations of specific genes that impact upon either the pharmacokinetics or pharmacodynamics of a given drug. In contrast, **pharmacogenomics** represents a focus on events at the level of the genome (e.g., gene–gene interaction) and how, in an integrated context, genetic constitution contributes to the variability in the exposure–response relationship.

Presystemic clearance (first-pass effect) occurs when a drug is either catabolized (e.g., through chemical degradation) or metabolized before it reaches the systemic circulation. Examples associated with oral drug administration include the pH-sensitive degradation of specific drugs in the stomach, drug biotransformation by enterocytes, enteral drug translocation by transporters, and enterohepatic drug recirculation. Presystemic drug clearance can also occur *ex vivo* (e.g., drug degradation and/or adsorption to tubing associated with cardiopulmonary bypass, extracorporeal membrane oxygenation). Drugs subject to first-pass effect (a classic example is propranolol) generally have a reduced rate and/or extent of relative bioavailability when compared to that achieved with parenteral administration.

Protein binding results when a drug combines with plasma, extracellular proteins, or tissue proteins to form a reversible drug–protein complex. In general, drug–protein binding is usually nonspecific and depends on the drug’s affinity for the protein molecule (i.e., binding site), the number of protein-binding sites, and the drug and protein concentration. With few exceptions, drugs that are bound to proteins are pharmacologically inactive and cannot be readily metabolized and/or excreted. Protein and/or tissue drug binding can also influence both the apparent volume of distribution and elimination $T_{1/2}$ of drugs that are extensively (i.e., >70%) bound, as well as their concentration–effect profiles (e.g., extent of plasma protein binding for amiodarone = 93% to 97%, sildenafil = 96%, and warfarin = 99%).

Steady state reflects a level of drug accumulation in blood and tissue upon multiple dosing when the rates of input (i.e., the amount of drug placed into the systemic circulation) and output (i.e., drug clearance) are at equilibrium. When drugs are given at fixed doses and dosing intervals, the steady-state

concentrations in blood or plasma fluctuate between a maximum (C_{\max}) and minimum (C_{\min}) within a given dose interval. The interdose values of C_{\max} and C_{\min} should be identical provided that dose size, method of drug administration, dosing interval, and/or drug pharmacokinetics do not change between doses. In general, the pharmacokinetics of a drug at steady state provides the most accurate means to assess drug effect(s) given that a proportional equilibrium between drug concentrations in the plasma and those at the effector sites(s) (i.e., receptors) should exist.

Therapeutic range represents a range of plasma drug concentrations (i.e., systemic exposure) associated with desirable therapeutic effect(s) and absent or minimal adverse effects. It may be influenced by factors that can modulate pharmacodynamics (e.g., age, disease, concomitant drugs, environmental exposures). The **therapeutic index** for a given drug reflects the relationship between the systemic exposure associated with desirable effects and that associated with the production of adverse effects. For drugs with a narrow therapeutic index such as digoxin, the difference between the systemic exposure (plasma levels) associated with therapeutic and adverse effects is small.

Trough drug concentrations (C_{\min}) represent those in plasma that occur immediately prior to a scheduled dose for drugs that are administered in repeated dosing regimens. The interdose excursion between C_{\max} and C_{\min} is a reflection of systemic drug exposure and in some instances, is associated with a “target” dosing strategy (e.g., cases in which a specific plasma drug concentration or AUC is associated with a desired pharmacodynamic effect).

Volume of distribution (VD) (apparent volume of distribution) represents a hypothetical volume of body fluid that would be required to dissolve the total amount of drug at the same concentration as that found in the blood. For drugs that do not distribute extensively or associate with great affinity to proteins and/or tissue, the VD may dimensionally correspond to a physiologic/anatomic body spaces (e.g., $VD < 0.1$ L/kg ~ intravascular space, 0.1 to 0.3 L/kg ~ extracellular space, 0.6 to 0.7 L/kg ~ total body water space). An apparent $VD > 1$ L/kg is suggestive of drugs with significant tissue binding (e.g., digoxin) that can influence its residence time in the body. Following extravascular drug administration, the apparent VD is impacted by the extent of drug absorbed (i.e., VD/F). In those instances where a drug has incomplete absorption, it may underestimate the true value of the VD.

THE EXPOSURE–RESPONSE RELATIONSHIP

Drug action results only when an exposure (both extent and duration of) occurs that is sufficient to translate a drug–receptor interaction into a physiologic response. Thus, the exposure–response relationship for a given drug represents an interface between pharmacokinetics and pharmacodynamics that can be conceptualized by simultaneous consideration of two profiles: (a) plasma concentration versus time (Figs. 79.1 and 79.2) and (b) plasma concentration versus effect (Fig. 79.2).

In the vast majority of instances, the relationship between drug concentration and effect is not linear. As illustrated in Figure 79.2 in the absence of drug in the body (i.e., at a concentration of zero), there is no discernable drug effect (E_0). Following drug administration, the concentration (both in the plasma and by inference, also at the receptor) increases as does the effect; first in an apparent linear fashion (at low drug concentrations) followed by a nonlinear increase in effect to an asymptotic point that reflects the maximal effect (E_{\max}) after which further increases in drug concentration are not associated with an increase in the desired drug effect. The drug

Figure 79.2. Representative nonlinear concentration (C) versus effect profile. Illustrated are E_{\max} , maximal effect; E_0 , the baseline effect associated with the absence of drug concentration; and EC_{50} , the concentration which is associated with an observed effect that is 50% of E_{\max} . (Reprinted from Abdel-Rahman SM, Kearns GL. The pharmacokinetic–pharmacodynamic interface: determinants of anti-infective drug action and efficacy in pediatrics. In: Feigin RD, Cherry JD, Demmler-Harrison GJ, et al., eds. *Feigin and Cherry's Textbook of Pediatric Infectious Disease*. 6th ed. Philadelphia, PA: Saunders-Elsevier, 2009:3158, with permission from Elsevier.)

concentration corresponding to 50% of the maximal effect is defined as the EC_{50} (Fig. 79.2); a pharmacodynamic term reflective of drug potency that is used to compare concentration–effect relationships between individuals and in some instances, between drugs in a given drug class. With rare exception, both E_{\max} and EC_{50} are rarely determined during therapeutic drug administration but rather are calculated pharmacodynamic parameters from research aimed at characterizing the dose–concentration–effect relationship.

With few exceptions, it is rarely possible to measure drug concentrations at or near the receptor. Therefore, it is necessary to utilize a surrogate measurement (e.g., direct measurement of blood pressure, blood glucose, electrocardiogram, echocardiography) to assess exposure–response relationships. In most instances, a change in a given surrogate measurement is examined in association with the plasma drug concentration versus time curve to assess pharmacodynamic properties. For drugs whose pharmacokinetic properties are best described by first-order (as opposed to zero- or mixed-order) processes, a semi-logarithmic plot of plasma drug concentration versus time data for an agent given by an extravascular route of administration (e.g., intramuscular, subcutaneous, intracasternal, intraperitoneal, peroral, transmucosal, transdermal, rectal) produces a pattern depicted by Figure 79.1. The ascending portion of this curve represents a time during which the liberation of a drug from its formulation, dissolution of the drug in a biologic fluid (e.g., gastric or intestinal fluid), and absorption of a drug are rate limiting relative to its elimination. After the time where maximal plasma concentrations (C_{\max}) are observed, the plasma concentration decreases as metabolism and elimination become rate limiting; the terminal portion of this segment of the plasma concentration versus time curve being representative of drug elimination from the body. Finally, the AUC can be determined by integrating the plasma concentration data over time.

By being able to characterize the pharmacokinetics of a specific drug, the clinician can use the data to individualize drug dosing regimens so as to compensate for factors that can influence pharmacokinetics (e.g., development, disease, concomitant treatment). For drugs where a therapeutic plasma

concentration range and/or “target” systemic exposure (i.e., AUC) is known, *a priori* knowledge of pharmacokinetic parameters for a given patient can facilitate the selection of a drug dosing regimen and thereby, optimize therapeutic response (e.g., cyclosporine, tacrolimus) (3). When linked with information regarding the pharmacodynamic behavior of a drug and the status of the patient (e.g., age, organ function, disease state, concomitant medications), the application of pharmacokinetics affords the practitioner the ability to exercise therapeutic decision making by enabling the selection of

a drug and dosing regimen that has the greatest likelihood of producing both efficacy and safety.

DEVELOPMENTAL PHARMACOKINETICS

For well over three decades, it has been known that physiologic changes that occur during human development produce alterations in drug disposition. As illustrated in Figure 79.3,

Figure 79.3. Developmental changes in physiologic factors that influence drug disposition in infants, children, and adolescents. **Panel A** illustrates age-dependent activity (relative to adult values) for important Phase I and Phase II enzymes responsible for drug biotransformation. **Panel B** illustrates developmental differences in body composition that can influence the apparent volume of distribution for drugs. **Panel C** illustrates the ontogeny of factors pertaining to gastrointestinal physiologic function, one or more of which can influence either the rate and/or extent of drug absorption. **Panel D** illustrates the acquisition of renal function (both glomerular filtration rate and active tubular secretory capacity reflected by para-aminohippuric acid clearance, a validated biomarker) during development. **Panel E** illustrates the impact of development on aspects of the integumentary system that collectively can modulate the systemic absorption of drugs applied to the skin. (From Kearns GL, Abdel-Rahman SM, Alander SW, et al. Developmental pharmacology—drug disposition, action and therapy in infants and children. *N Engl J Med* 2003;349:1157–1167, Copyright © 2003 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

maturation can produce, especially in early life, dramatic physiologic changes that impact drug absorption, distribution, metabolism, and excretion. Accumulated information supports that many of these changes are indeed predictable (4) and consequently, they can be used to inform the design of pediatric clinical trials through the use of modeling and simulation and also, to clinically individualize drug treatment for a given patient based on known or expected pharmacokinetic behavior of a given drug (5). An example of therapeutic utility of pharmacokinetic-based optimization of drug treatment has been recently illustrated in the provision of antiretroviral therapy in children (6).

For the clinical application of such data, it is important for the clinician to have a conceptual understanding of how development influences both drug disposition and effect. In the following paragraphs, we provide a summary of developmental pharmacokinetics, much of which has been excerpted (with permission) from recent works (1,7,8) published by one of the coauthors (G.L.K.). These publications can be referred to for reference to citations in the primary literature upon which the following summaries are based.

Drug Absorption

Absorption of drugs administered by extravascular routes occurs largely via passive diffusion. At certain anatomical sites where drug transport proteins are expressed, absorption can occur via active transport or facilitated diffusion. In addition to physiologic changes that occur during development, the concomitant presence of certain disease states (e.g., inflammatory bowel disease, diarrhea) can produce changes in either the rate or extent of drug absorption. A summary of important

factors that can influence drug absorption in neonates, infants, and children is provided in Table 79.1.

Oral Absorption

As is the case in adults, most therapeutic drugs administered in the outpatient setting are given by the oral route. During development, maturational changes of gastric, intestinal, and biliary tract function (Fig. 79.3, panel C) occur and either singly or collectively can impact the rate and extent of drug absorption.

Given that most orally administered drugs have the physicochemical property of being either a weak acid or weak base, pH within the gastrointestinal tract can influence the amount of potentially absorbable drug (i.e., the un-ionized moiety existing in a true solution) available. As illustrated in Figure 79.3 (panel C), gastric hydrochloric acid production changes as a function of age. Gastric pH changes significantly throughout development with the highest values occurring during the neonatal period. In the fully mature neonate, the gastric pH ranges from 6 to 8 at birth and drops to 2 to 3 within a few hours of birth. However, after the first 24 hours of postnatal life, the gastric pH increases due to the immaturity of the parietal cells and gradually reaches expected adult values (e.g., gastric pH 2 to 3) by approximately 2 to 3 years of age. As a result of these developmental differences, the bioavailability of acid-labile drugs (e.g., penicillin, ampicillin) is increased (relative to older children and adults) in neonates and young infants, whereas the absorption of weak organic acids is decreased. For drugs with a relatively narrow therapeutic index (e.g., phenytoin), the ontogeny of gastric pH can produce significant age-associated alterations in bioavailability that may necessitate more frequent alterations in drug dosing regimens required to achieve therapeutic plasma levels.

TABLE 79.1

Summary of Important Factors that Influence Drug Absorption in Neonates, Infants, and Children

	Neonates	Infants	Children
<i>Physiologic alteration</i>			
Gastric emptying time	Irregular	Increased slightly	Increased
Gastric pH	>5	4–2	Adult pattern
Intestinal motility	Reduced	Increased	Slightly increased
Intestinal surface area	Reduced	Near adult	Adult pattern
Microbial colonization	Reduced	Near adult	Adult pattern
Biliary function	Immature	Near adult	Adult pattern
Muscular blood flow	Reduced	Increased	Adult pattern
Skin permeability	Increased	Increased	Near adult pattern
<i>Possible pharmacokinetic consequences</i>			
Oral absorption	Erratic—reduced	↑ rate	Near adult pattern
IM absorption	Variable	Increased	Adult pattern
Percutaneous absorption	Increased	Increased	Near adult pattern
Rectal absorption	Very efficient	Efficient	Near adult pattern
Presystemic clearance	< adult	> adult	> adult (↑ rate)

Direction of alteration given relative to expected normal adult patterns.

Reprinted from Ritschel WA, Kearns GL. Definitions and nomenclature. In: Ritschel WA, Kearns GL, eds. *Handbook of Basic Pharmacokinetics... Including Clinical Applications*, 7th ed. Washington, DC: American Pharmacists Association, 2009:1–10; Table 24.1, with permission.

During development, one of the most important physiologic changes capable of altering the rate of drug absorption resides with gastrointestinal motility. During early infancy, gastric emptying time is prolonged, which can delay delivery of orally administered drugs to the small intestine where the majority of absorption takes place. By 6 to 8 months of age, gastrointestinal transit times may be shorter than those observed for older children and adults; a situation which can significantly influence both the rate and extent of bioavailability of drugs with limited water solubility (e.g., phenytoin, carbamazepine) by reducing residence time at the absorptive sites in the small intestine. Lastly, immature biliary function in neonates and young infants in the first few months of life has the potential for reducing the extent of oral bioavailability of lipophilic drugs that are dependent upon bile acids for their solubility in the small intestine (e.g., fat-soluble vitamins).

Developmental differences in the activity of intestinal drug-metabolizing enzymes (e.g., CYP3A4/5, CYP1A, *N*-acetyltransferase, xanthine oxidase, and glutathione-*S*-transferase) and efflux transporters (e.g., P-glycoprotein or MDR1) can markedly alter the bioavailability of some orally administered drugs. While the patterns of ontogeny for these enzymes and transporters are not concordant, the majority appear to have adult expression within the first 6 to 12 months of postnatal life at which time the influence of development on their activity as a determinant of bioavailability would be expected to be minimal.

Extravascular Drug Absorption

As is the case with oral drug absorption, development can influence the bioavailability of drugs administered by other extravascular routes (e.g., subcutaneous, intramuscular, introsseous, intratracheal, intraperitoneal, rectal, dermal) largely as a result of changes in regional blood flow and tissue composition (Table 79.1). In the neonate, muscular blood flow is reduced in the first few days of life, as is the relative efficiency of muscular contractions. Furthermore, neonates and young infants have greatly reduced muscle mass (compared to older infants and children) and increased percentage of water per unit of muscle mass. Collectively, these developmental changes can produce variable and delayed rates of absorption of drugs given by the intramuscular route.

In contrast, mucosal (rectal and buccal) and dermal permeability in the neonate and young infant is increased and thus may result in enhanced absorption by these routes. In the case of transdermal drug absorption, a more highly perfused and hydrated stratum corneum (Fig. 79.3, panel E) facilitates drug absorption in the neonate and very young infant. In addition, the ratio of body surface area to body weight is greater in infants and children as compared to adults. Collectively, these developmental differences may predispose infants and young children in the first 8 to 12 months of life to increased exposure and risk for toxicity for drugs/chemicals placed on the skin (e.g., silver sulfadiazine, topical corticosteroids, benzocaine, diphenhydramine, isopropyl alcohol).

Normal developmental differences in drug absorption from almost all extravascular routes of administration can influence the dose–plasma concentration relationship in a manner sufficient to alter pharmacodynamics. Disease states that affect the integrity of the physiologic barriers that drugs given by extravascular routes must traverse prior to their translocation to the vascular space must be considered, as they can influence both the rate and extent of drug absorption. Finally, with regard to extravascular drug administration, it must be recognized that the onset of drug effect is directly dependent upon the route of administration. For example, the onset of effect for most drugs given intravenously is, in most cases, virtually instantaneous. This is contrasted with drugs given by inhalation (onset ~ 2 to 3 minutes), sublingual administration (onset ~ 3 to 5 minutes), intramuscular injection

(onset ~ 10 to 20 minutes), subcutaneous injection (onset ~ 15 to 30 minutes), rectal (onset ~ 30 minutes), oral (onset ~ 30 to 90 minutes), and transdermal (onset ~ minutes to hours) routes.

Drug Distribution

Drug distribution is influenced by a variety of factors including drug-specific physicochemical properties, tissue composition (e.g., water, fat, and lean muscle content) and perfusion, the role of drug transporters, blood/tissue protein binding, blood, and the pH of blood and tissue fluids. To a great degree, changes in drug distribution during development are associated with changes in body composition and the quantity of plasma proteins capable of drug binding. As well, certain disease states (e.g., ascites, dehydration, burn injuries involving large surface area, sepsis with capillary leak syndrome) can influence body water compartment sizes and thereby, the distribution of drugs with an apparent volume of distribution less than or equal to the total body water space (i.e., 0.6 L/kg).

As illustrated in Figure 79.3 (panel B), neonates and young infants have significantly higher total body water and extracellular water spaces than older infants and children. The reduction in relative total body water occurs rapidly during the first year of life, and by 12 years, adult values (i.e., ~60% of lean muscle mass) are attained. In contrast, the percentage of intracellular water as a function of body mass remains stable from the first months of life through adulthood. For drugs that are primarily distributed to a space that approximates the extracellular fluid pool and are not highly bound to plasma proteins (e.g., aminoglycoside antibiotics), their weight-adjusted apparent volumes of distribution (i.e., L/kg) are larger (e.g., approximately 0.4 to 0.6 L/kg in neonates and infants vs. 0.2 to 0.3 L/kg in adults), which necessitates the administration of higher weight-adjusted (mg/kg) doses in order to attain target plasma (blood) levels.

Despite the relatively low body fat content in the neonate (~16%, Fig. 79.3, panel B), the developing central nervous system (CNS) has a relatively high lipid content in early life; a condition with implications for the distribution of lipophilic drugs capable of acting in the CNS. The body fat percentage tends to increase up to about 10 years of age and then changes composition with respect to puberty and sex. In normal children and adolescents with age-appropriate body habitus, changes in body composition beyond the first 3 months of life do not appear to produce profound developmental differences in drug disposition. This does not appear to be the case for obese children in whom increased body fat appears to require adjustment in the normal age-appropriate dosing regimen for several drugs (e.g., aminoglycosides, carbamazepine, phenytoin, benzodiazepines, digoxin, lithium, opiates) (9).

Of the circulating proteins in plasma, albumin (which preferentially binds weak acids) and α_1 -acid glycoprotein (which preferentially binds weak bases) are quantitatively the most important for drug binding. As summarized in Table 79.2, the concentration of these proteins changes over development with low concentrations in the neonate and young infant (~80% of adult), increasing to adult values by approximately 1 year of age. A similar pattern of maturation is observed with α_1 -acid glycoprotein where neonatal plasma concentrations are approximately three times lower than in maternal plasma and attain adult values by approximately 1 year of age. Additionally, specific conditions (e.g., malnutrition, protein-losing enteropathy, nephrotic syndrome, large burn injuries, extravascular translocation of proteins, sepsis, acidosis, protracted hyperglycemia, chronic renal failure with uremia) can reduce the absolute concentration of drug-binding proteins and in some instances (e.g., acidosis, glycation of albumin associated with chronic hyperglycemia, carbamylation of albumin associated with uremia), the binding affinity of a given drug

TABLE 79.2

Ontogenic Influences of Plasma Drug–Protein Binding and Drug Distribution

	Neonates	Infants	Children
<i>Physiologic alteration</i>			
Plasma albumin concentration	Reduced	Near normal	Near adult pattern
Fetal albumin concentration	Present	Absent	Absent
Total protein concentration	Reduced	Decreased	Near adult pattern
Total globulin concentration	Reduced	Decreased	Near adult pattern
Serum bilirubin	Increased	Normal	Normal adult pattern
Serum free fatty acids	Increased	Normal	Normal adult pattern
Blood pH	7.1–7.3	7.4 (normal)	7.4 (normal)
Adipose tissue	Scarce (↑ CNS)	Reduced	Generally reduced
Total body water	Increased	Increased	Near adult pattern
Extracellular water	Increased	Increased	Near adult pattern
Endogenous maternal substances (ligands)	Present	Absent	Absent
<i>Possible pharmacokinetic consequences</i>			
Free drug fraction	Increased	Increased	Slightly increased
<i>Apparent volume of distribution</i>			
Hydrophilic drugs	Increased	Increased	Slightly increased
Hydrophobic drugs	Reduced	Reduced	Slightly decreased
Tissue/plasma ratio	Increased	Increased	Slightly increased

Direction of alteration given relative to expected normal adult patterns.

Reprinted from Ritschel WA and Kearns GL. *Handbook of Basic Pharmacokinetics*. 7th ed. Washington, DC: American Pharmacists Association, 2009, with permission.

for a protein. Binding affinity for acidic drugs is also reduced in the neonate as a consequence of the higher concentrations of fetal albumin (which has a lower binding capacity) and endogenous substances (e.g., bilirubin) that can compete with drugs for albumin binding sites. For example, circulating fetal albumin in the neonate has significantly reduced binding affinity for acid drugs such as phenytoin that is extensively (~94% to 98%) bound to albumin in adults as compared to 80% to 85% in the neonate. The resultant six- to eightfold difference in the free fraction can result in CNS adverse effects in the neonate when total plasma phenytoin concentrations are within the generally accepted “therapeutic range” (10 to 20 mg/L), thereby influencing the pharmacodynamics of this agent.

Drug transporters, such as P-glycoprotein, MDR1, and MDR2 (multidrug resistance 1 or 2), can also influence drug distribution. These drug transporters can markedly influence the extent to which drugs cross membranes in the body and whether drugs can penetrate or are secreted from the target sites. While there are limited data on the ontogeny of drug transport proteins, available information demonstrates their presence as early as 22 weeks’ gestation and low levels in the neonatal period that rapidly increase to adult values by 1 to 2 years of age.

Drug Metabolism

Metabolism reflects the biotransformation of an endogenous or exogenous molecule by one or more enzymes to moieties that generally are more polar (hydrophilic) and thereby, more

easily eliminated via excretion, secretion, and/or exhalation. While in many cases, drug metabolism results in pharmacologic inactivation of a drug, there are instances where it can either contribute to or be a determinant of drug action. The former situation is illustrated by drugs that have pharmacologically active metabolites (e.g., metabolism of amitriptyline to nortriptyline, codeine to morphine) and the latter, by the example of prodrugs where an inactive moiety is biotransformed to an active agent (e.g., enalaprilat). It should be noted that metabolic activation for some drugs has been identified as a mechanism underlying toxicity (e.g., acetaminophen-associated hepatotoxicity; Stevens-Johnson syndrome associated with sulfonamides, phenytoin, and carbamazepine; halothane-associated hepatitis).

Quantitatively, the most important organ responsible for drug biotransformation is the liver. However, drug-metabolizing enzymes (e.g., phosphatases, esterases) also exist in the blood, brain, lung, small intestine, adrenal glands, kidney, and skin. Drug metabolism has historically been conceptualized as occurring via two general classes of enzymatic processes: **Phase I**, or nonsynthetic reactions (e.g., oxidation, reduction, hydrolysis, hydroxylation) and **Phase II**, or synthetic (e.g., glycine, glucuronide, glutathione, sulfate conjugation) reactions. It is important to note that in many instances, Phase I and Phase II reactions can occur sequentially (e.g., hydroxylation of drug molecule followed by glucuronidation of the primary metabolite) as most all therapeutic drugs are polyfunctional substrates for a variety of drug-metabolizing enzymes. At birth, the concentration of drug-oxidizing enzymes in fetal liver (corrected

for liver weight) appears similar to that in adult liver. However, the activity of these oxidizing enzyme systems is reduced, which results in slow clearance (and prolonged elimination) of many drugs. Finally, as illustrated by Figure 79.3 (panel A), both Phase I and II drug-metabolizing enzymes have an ontogenic profile that generally is reflective of maturation over a period of months to years with different enzymes having specific developmental trajectories. For example, alcohol dehydrogenase (ADH1C) is expressed at extremely low levels in the fetus but increases dramatically in the first 1 to 2 years after birth. In contrast, CYP3A7, a cytochrome P450 (CYP450) responsible for the biotransformation of the endogenous substrate dihydroepiandrosterone sulfate (DHEA-S), is expressed at the highest level during the first trimester, whereas its activity at 1 to 2 years of age is virtually absent in most individuals. Finally, one of the isoforms of sulfotransferase (SULT1A1) is expressed at relatively constant levels during gestation and postnatal life (10).

The impact of ontogeny on the activity of human drug-metabolizing enzymes has been the topic of several reviews (11–13). Of the many enzymes capable of metabolizing drugs and other small molecules, the CYP450 supergene family is quantitatively the most important. Specific CYP450 isoforms (and prototypical drug substrates) responsible for the majority of drug metabolism in humans include CYP1A2 (caffeine), CYP2C9 (warfarin, losartan, phenytoin), CYP2C19 (proton pump inhibitors, clopidogrel), CYP2D6 (codeine, tamoxifen), CYP2E1 (ethanol), CYP3A5 (tacrolimus), and CYP3A4 (midazolam, cyclosporine).

Compared to Phase I drug-metabolizing enzymes, the impact of development on the activity of Phase II enzymes is not as well characterized. However, studies to date indicate that in general, Phase II enzyme activities are decreased in the newborn and increase in childhood. For example, conjugation of compounds metabolized by UDP-glucuronosyltransferase (UGT) isoforms (e.g., morphine, bilirubin, and chloramphenicol) illustrates reduced metabolic capacity at birth that in turn can dramatically reduce drug plasma clearance (e.g., the gray baby syndrome tragedy associated with excessive systemic exposure to chloramphenicol following the administration of “normal” pediatric doses to neonates and young infants). Development of metabolic competence for most Phase II drug-metabolizing enzymes occurs rapidly during the first year of life and for selected enzymes can exceed adult values by 3 to 4 years of age (12). As illustrated by data for human glucuronosyltransferases (14), the impact of ontogeny on drug-metabolizing enzyme activity can be isoform specific. For example, the activity of the UGT isoforms responsible for acetaminophen metabolism (UGT1A1 and UGT1A9) is markedly reduced in neonates and infants, and as a result, conjugation of the drug metabolites is primarily dependent upon glutathione transferase and sulfotransferase isoforms. As infants develop, UGT activity increases and by the first year of life, these enzymes become the most quantitatively important for acetaminophen metabolism. A similar developmental profile exists for morphine, a drug whose metabolism is largely dependent upon two polymorphically expressed UGT isoforms, UGT2B7 and UGT1A1 (15).

Many drug-metabolizing enzymes represent the products of genes that in some instances, are polymorphically expressed, with the variant alleles often conveying reduced and/or absent activity. A notable exception is exemplified by the CYP2C19*17 allele that appears to convey increased catalytic activity to the enzyme (16). Similarly, polymorphic expression of genes responsible for regulation of specific drug transporter proteins also exists. Together with drug-metabolizing enzymes, their activities are often the rate-limiting event for metabolic clearance of a drug from the body and, in some instances, for drug action. Thus, genetic polymorphisms can influence both the pharmacokinetics and pharmacodynamics of drugs.

The potential clinical importance of genetic polymorphisms for a drug-metabolizing enzyme has been recently illustrated by a comprehensive review published by Swen et al. (17) that discusses CYP2D6 phenotype and its relevance to the therapeutic use of flecainide, metoprolol, and propafenone. As illustrated by Table 79.3, differences in the pharmacokinetics of these drugs associated with CYP2D6 phenotype (i.e., poor-metabolizer, intermediate metabolizer, or ultrarapid metabolizer; each conveyed by specific allelic variants of the CYP2D6 gene) must be considered in the selection of a dosing regimen so as to prevent either therapeutic failure (e.g., subtherapeutic systemic exposure resulting from a “normal” dose given to an individual with rapid drug clearance consequent to having an ultrarapid CYP2D6 metabolizer phenotype) or therapeutic misadventure (e.g., increased systemic exposure associated with drug toxicity in individuals having a poor-metabolizer CYP2D6 phenotype). A recent review published by Visscher et al. (18) also highlights the importance of polymorphic expression of genes responsible for the expression of drug-metabolizing enzymes, transporters, and receptors. As summarized in Table 79.4 with the example of warfarin, allelic variants of the enzyme primarily responsible for its metabolism (i.e., CYP2C9) and also for its mechanism of action (i.e., VKORC1 or vitamin K epoxide reductase) require therapeutic dose adjustment in order to prevent excessive coagulation. In contrast, the example of clopidogrel illustrates that polymorphic expression of both the primary drug-metabolizing enzyme (i.e., CYP2C19) and the efflux transporter ABCB1 (also called MDR1 or P-glycoprotein) serve as determinants of therapeutic dosing regimens. Finally, the importance of genetic polymorphism on pharmacodynamics is well illustrated by the β -adrenergic receptor blockers where variant alleles of the β -receptor are associated with either an improved response to therapy or, alternatively, an increased likelihood of adverse events that are dependent upon a specific genotype.

In addition to their importance in removing drugs from the body, it is important to recognize that both drug-metabolizing enzymes and transporters that exist predominantly in the small intestine and both their polymorphic and ontogenic expression can alter the absolute bioavailability of drugs. Like drug-metabolizing enzymes, the activity of intestinal drug transporters (MDR1 or P-glycoprotein) is low at birth (relative to adults) and increases throughout the first 2 years of life (19). Given that the activity of most drug-metabolizing enzymes is markedly reduced in the neonate, the extent of bioavailability of drugs that are substrates for drug-metabolizing enzymes (e.g., CYP3A4, CYP3A5) and transporters (ABCB1) in the small intestine would be expected to be increased during the first weeks of life. Presystemic clearance (also described as first-pass effect) would increase as the functional capacity of these proteins increases, with the potential for reducing the bioavailability of drugs given by the oral route. Unfortunately, very few bioavailability studies are conducted in infants and children; thus, assumptions regarding the impact of ontogeny on presystemic drug clearance must be made based on the known developmental profiles and pharmacogenomics for the drug-metabolizing enzymes and transporters involved (20). Thus, estimates of how presystemic clearance may influence drug bioavailability derived from adult studies cannot be accurately applied to extrapolate how a drug dose given by the oral route may need to be age-adjusted for a neonate or infant.

Table 79.5 summarizes the physiologic alterations during development that contribute to drug metabolism and also their potential pharmacokinetic consequences. However, with regard to predicting the impact of development on drug metabolism, it is the isoform-specific ontogenic profile for each enzyme and transporter involved that must be considered in deducing how developmental differences *per se* can effect drug clearance as a determinant of the exposure–response relationship.

TABLE 79.3

Examples of Cardiovascular Drugs where Polymorphic Gene Expression of CYP2D6 in Adults Supports Modification of Dosing Regimen

Drug	Genotype or Phenotype	Level of Evidence	Clinical Relevance	Impact on Dosing Recommendations
Flecainide	PM	Good from controlled studies	Minor clinical effect	Reduce dose by 50%, record ECG, monitor plasma concentration
	IM	—	—	Reduce dose by 25%, record ECG, monitor plasma concentration
	UM	—	—	Record ECG, monitor plasma concentration
Metoprolol	PM	Good from controlled studies	Long-standing, significant implications	Production of heart failure. Select alternative drug or reduce dose by 75% and monitor for drug-associated adverse events
	IM	Good from controlled studies	Short lived with mild implications	Actively monitor for drug-associated adverse events
	UM	Good from controlled studies	Long-standing, significant implications	Heart failure due to subtherapeutic exposure. Select alternative drug or titrate to maximum of 250% of the normal dose
Propafenone	PM	Good from controlled studies	Long-standing, significant implications	Reduce dose by 70%, record ECG and monitor plasma concentrations
	IM	Moderate from published studies	Moderate clinical effect	Insufficient data to allow for dose calculation. Record ECG and adjust dose to plasma concentration or select alternative drug
	UM	Moderate from published studies	Minor clinical effect	Insufficient data to allow for dose calculation. Record ECG and adjust dose to plasma concentration or select alternative drug

PM, poor metabolizer; IM, intermediate metabolizer; and UM, ultrarapid metabolizer.

Pharmacogenetics: from bench to byte—an update of guidelines. *Clin Pharmacol Ther* 2011;89:662–673, where evidence level and clinical relevance for specific examples are further defined and references to applicable primary literature are provided.

TABLE 79.4

Overview of Drug-Metabolizing Enzyme and Transporter Gene Variants and their Association with Cardiovascular Drug Response

Drug (class)	Gene	Variants	Effect(s)
Warfarin	<i>CYP2C9</i>	*2	Decreased enzyme activity, reduced daily dose requirement
	<i>CYP2C9</i>	*3	Markedly reduced enzyme activity, reduced daily dose requirement
	<i>VKORC1</i>	–1639G>A	Reduced gene expression, increased drug susceptibility, need for reduced dose requirement
Clopidogrel	<i>CYP2C19</i>	*2	Decreased enzyme activity, increased dose requirement, reduced drug response
	<i>CYP2C19</i>	*3	Decreased enzyme activity, increased dose requirement
	<i>CYP2C19</i>	*4	Decreased enzyme activity, increased dose requirement
	<i>CYP2C19</i>	*5	Decreased enzyme activity, increased dose requirement
	<i>ABCB1</i>	3435C>T	Reduced plasma levels of active metabolites, increased dose requirement
β-Blockers	<i>ADRB1</i>	Ser49Gly	Improved drug response in Gly49 carriers
	<i>ADRB1</i>	Arg389Gly	Improved response in Arg/Arg homozygotes
	<i>ADRB2</i>	Gly16Arg and Gln27Glu	Increased risk of adverse outcomes in Gly16/Gln27 haplotype carriers
	<i>ADRA2C</i>	Deletion of amino acids 322–325	Improved response to metoprolol in deletion carriers when combined with <i>ADRB1</i> Arg/Arg phenotype

CYP refers to specific cytochrome P450 isoforms; ABCB1 refers to P-glycoprotein; ADRB1 and ADRB2 refer to the β-1 and β-2 adrenergic receptor, respectively, and ADRA2C refers to the α-2c-adrenergic receptor.

TABLE 79.5 Drug Metabolism in the Neonate, Infant, and Child

	Neonates	Infants	Children
<i>Physiologic alteration</i>			
Liver/body weight ratio	Increased	Increased	Slightly increased
Cytochrome P450 activity	Reduced	Increased	Slightly increased
Blood esterase activity	Reduced	Normal (by 12 mo)	Adult pattern
Hepatic blood flow	Reduced	Increased	Near adult pattern
Phase II enzyme activity	Reduced	Increased	Near adult pattern
<i>Possible pharmacokinetic consequences</i>			
Metabolic rates	Reduced	Increased	Near adult pattern ^a
Presystemic clearance	Reduced	Increased	Near adult pattern
Total body clearance	Reduced	Increased	Near adult pattern ^a
Inducibility of drug-metabolizing enzymes	More evident	Slightly increased	Near adult pattern ^a

Direction of alteration given relative to expected normal adult patterns. ^aDenotes assumption of adult pattern of activity after the conclusion of puberty. The activity of all drug-metabolizing enzymes is generally higher before versus after puberty.

Renal Drug Elimination

The kidney is the primary organ responsible for the excretion of drugs and their metabolites. The development of renal function begins during early fetal development and is complete by early childhood (Fig. 79.3, panel D). From a developmental perspective, renal function is highly dependent on gestational age and postnatal adaptations. Renal function begins to mature early during fetal organogenesis and is complete by early childhood. Increases in glomerular filtration rate (GFR) result from both nephrogenesis, a process that is completed by 36 weeks of

gestation, and changes in renal and intrarenal blood flow (21). GFRs vary widely among different postconceptional ages and range from approximately 2 to 4 mL/min/1.73 m² in term neonates to a low of 0.6 to 0.8 mL/min/1.73 m² in preterm neonates. The GFR increases rapidly during the first 2 weeks of life and then more slowly until adult values are reached by 8 to 12 months of postnatal age (22,23). Development impacts not only GFR but also tubular secretion, which is immature at birth and reaches adult capacity during the first year of life (Fig. 79.3, panel D).

Developmental changes that occur in renal function are better characterized than any other organ system (Table 79.6).

TABLE 79.6 Renal Function in the Neonate, Infant, and Child

	Neonates	Infants	Children
<i>Physiologic alteration</i>			
Kidney/body weight ratio	Increased	Increased	Near adult values
Glomerular filtration rate	Reduced	Normal (by 12 mo)	Normal adult values
Active tubular secretion	Reduced	Near normal	Normal adult values ^a
Active tubular reabsorption	Reduced	Near normal	Normal adult values
Proteins present in urine	Present	Low to absent	Normally absent
Urinary acidification capacity	Low	Normal (by 1 mo)	Normal adult activity
Urine output (mL/h/kg)	3–6	2–4	1–3
Urine concentrating capacity	Reduced	Near normal	Normal adult values
<i>Possible pharmacokinetic consequences</i>			
Active drug excretion	Reduced	Near normal	Normal adult pattern
Passive drug excretion	Reduced to increased	Increased	Normal adult pattern
Excretion of basic drugs	Increased	Increased	Near normal

Direction of alteration given relative to expected normal adult patterns.

^aDenotes slight increase in excretion rate for basic compounds.

For drugs that have substantial renal clearance, kidney function serves as a major determinant of age-specific drug dosing regimens. Failure to account for the ontogeny of renal function and adjust dosing regimens accordingly can result in a degree of systemic exposure that can increase the risk of drug-associated adverse events. A well-characterized example resides with digoxin. Consequent to its predominant renal elimination, the plasma clearance of digoxin is markedly reduced in the neonate and young infant, and only approaches adult values when both GFR and active tubular secretory capacity mature (Fig. 79.3, panel D) (24). Failure to adjust the dose and dosing interval for digoxin to compensate for developmentally associated differences in its plasma clearance can produce significant toxicity, especially given the low therapeutic index for this drug (25). Another example resides with gentamicin where a starting dosage interval of 12 hours in infants of any gestational age or a starting dosage interval of 24 hours for infants of <30 weeks' gestational age has been shown to lead to serum gentamicin trough levels in the toxic range (26). It is also important to note that use of some medications concomitantly (i.e., betamethasone and indomethacin) may cause alteration of the normal pattern of renal maturation in the neonate (27). Therefore, both maturation and effects of treatment with regard to renal function are important considerations when determining appropriate drug treatments in neonates and infants.

DEVELOPMENTAL PHARMACODYNAMICS

When one considers the impact of development on the exposure–response relationship for a given drug, it is important to realize that these do not simply occur consequent to pharmacokinetic differences (e.g., increased systemic drug exposure resulting from age-associated reduced drug clearance). As recently reviewed by Mulla (28), development can influence pharmacodynamics through consequences of maturational changes in drug receptor number, receptor affinity, receptor density, signal transduction, or alterations in the intracellular milieu necessary for the creation of a pharmacologic effect. For example, a previous study performed using lymphocytes harvested from pediatric patients from infancy through adolescence demonstrated a markedly enhanced sensitivity to the effects of cyclosporine (i.e., significant reduction in EC_{50}) in infants as compared to older children and adults (29). A more recent study of sotalol pharmacodynamics in children with supraventricular tachycardia (30) demonstrated that neonates had a higher sensitivity toward drug-associated QTc interval prolongation, which in turn supported the use of a lower starting dose for the drug as compared to older infants and children. In addition to desired therapeutic drug effects, age-dependent pharmacodynamics are illustrated through the consideration of several well-known clinical adverse drug reactions. For example, the susceptibility to metoclopramide-associated movement disorders (e.g., dystonias, bradykinetic reactions) is much higher in infants <2 years of age and diminishes with maturation into the second decade of life (28). Similarly, ontogenic profiles appear to be operative for valproic acid-associated hepatotoxicity (31), midazolam-associated sedation (32), and warfarin sensitivity (33,34), all of which are examples where age-associated differences in drug response appear independent of pharmacokinetic alterations.

As also reviewed by Mulla (28), much of the data concerning developmental pharmacodynamics are derived from animal studies. However, there are instances where human and animal correlates have been established. Examples include differences in gamma-aminobutyric acid type A ($GABA_A$) receptor density associated with paradoxical seizures evoked by antiepileptic drugs in children and increased sensitivity to immunosuppressant drugs associated with maturational

changes in the immune system. The paucity of developmental pharmacodynamic information in humans resides with a relative absence of validated, functional biomarkers capable of quantitating differences in drug action that are suitable for longitudinal use across the spectrum of human development. Finally, it is important to recognize that perceived developmental differences in both pharmacokinetics and pharmacodynamics can be influenced by the concomitant expression of disease whereby observations made during the “well” state can be very different from those during both acute (e.g., multiorgan system disease associated with sepsis) and chronic phases of a given illness (e.g., vascular endothelial changes associated with long-standing diabetes and sickle cell disease).

DEVELOPMENTAL PHARMACOGENOMICS

Developmental pharmacogenomics represents the intersection of normal human development and genetic constitution as determinants of drug disposition and/or action. In healthy adults, the interpretation of genotype–phenotype relationships is largely two dimensional given that the genotype is “fixed” (with the exception of epigenetic events) and absent external modifiers (e.g., concomitant disease and/or drug treatment), the expression of phenotype is invariant. This is not the case in the developing human where ontogeny of processes governing either pharmacokinetics (e.g., drug-metabolizing enzymes, transporters) or pharmacodynamics (e.g., receptor expression, signal transduction) can add a third dimension in the interpretation of the genotype–phenotype relationship. As recently denoted by Neville et al. (35), the impact of ontogeny on the genotype–phenotype relationships for drug-metabolizing enzymes, transporters, and/or receptor expression has in most cases not been explored experimentally across the continuum of development or reduced to age- and genotype-specific treatment guidelines for pediatric patients. In instances where these relationships have been evaluated, pharmacologic probe substrates (i.e., drugs whose biotransformation occurs preferentially by a given enzyme) have been used and pharmacokinetic data (either clearance or elimination rate) have been employed as a surrogate to assess the impact of development on the activity of one or more drug-metabolizing enzymes (14,36,37). Despite the fact that the U.S. Food and Drug Administration has included pharmacogenetic data (predominantly derived from adult studies) in the approved product labels for approximately 10% of drugs sold in the United States (38), the clinical utility of these data in pediatric therapeutic decision making can be quite limited. Specifically, understanding the developmental trajectory for the functional activity of genes as well as the developmental context in which the gene(s) of interest is/are operating is of paramount importance when considering the predictive nature of genotype related to either drug disposition or action, both therapeutic and adverse (39).

As intimated above, when genotype and phenotype are concordant, genotype can theoretically be used to predict the activity of a drug-metabolizing enzyme or transporter (i.e., the phenotype). This has been demonstrated for CYP2D6 where an “activity score” predictive of enzyme activity was constructed following consideration of over 25 different allelic variants and their functional consequences (40). The potential clinical utility involved with the use of genotype-derived activity scores for a specific drug metabolism is when the score can be demonstrated to be a reliable predictive biomarker of drug clearance.

As denoted previously, maturation of metabolic capacity for a given drug-metabolizing enzyme or transporter has a specific developmental trajectory with functional maturity (i.e., that observed in healthy adults) generally attained within the first decade of life (4). In those instances where the enzyme

of interest is functionally mature (i.e., a metabolic capacity observed in a healthy adult), concordance of genotype and phenotype can enable the use of allometric scaling to predict drug clearance and age-appropriate drug dose based on weight throughout the pediatric age spectrum. However, as recently denoted by Holford (41), predictive accuracy of allometric scaling is compromised during periods of development where the activities of pathways responsible for drug clearance (e.g., enzymes, transporters, renal elimination processes) are immature. The extension of this principle to the arena of developmental pharmacogenomics is exemplified by periods of life where the maturation of drug clearance pathways/mechanisms demonstrates genotype–phenotype discordance. This is illustrated by data for pantoprazole, a proton pump inhibitor that, in both adults and children, is predominantly metabolized by the polymorphically expressed enzyme, CYP2C19 (16).

Figure 79.4 illustrates apparent plasma clearance (CL/F) data for pantoprazole from a population of neonates (both preterm and term) (42), children, and adolescents (43) with a clinical diagnosis of gastroesophageal reflux disease. Examination of the CL/F data for infants from this study with a postnatal age of <5 weeks showed no difference in the parameter between one patient with a CYP2C19 genotype predictive of a poor-metabolizer phenotype and those with a CYP2C19 genotype corresponding to an extensive-metabolizer phenotype. Beyond a postnatal age of 5 weeks, the pantoprazole CL/F values increase commensurate with previously reported maturational profiles for CYP2C19 (44) and as a result, concordance between CYP2C19 genotype and phenotype occurs. Thus, as reflected by this example, genotyping results for CYP2C19 obtained during the first month of life would not be expected to be predictive of the clearance of drugs that are substrates for this enzyme until such time that genotype and phenotype were concordant.

Finally, it should be recognized that during development, maturation of functional capacity for drug-metabolizing

enzymes (or transporters) is not the only “event” capable of modulating the genotype–phenotype relationship. Relevant examples include the potential impact of diet as reflected by the previously reported differential effect of breast milk versus formula feeding on the developmental acquisition of CYP1A2 activity (36) and the potential of therapeutic drugs to alter the activity of a drug-metabolizing enzyme (e.g., induction of CYP3A4/5 by rifampin and inhibition of the enzyme(s) by erythromycin or azole antifungal agents).

CARDIOVASCULAR DRUGS

It is beyond the scope of this chapter to provide an exhaustive detailed description of every drug used to treat every conceivable cardiovascular condition. Instead, we provide an overview of the general classifications and mechanisms of action of the most commonly used cardiovascular drugs in the pediatric population. Information regarding drug dosing is available in standard references (45). More disease-specific drug information and additional details are available in accompanying chapters dealing with cardiac transplantation, arrhythmias, heart failure, myocarditis, hypertension, and hyperlipidemias.

CARDIAC GLYCOSIDES

Digoxin

Digoxin is the cardiac glycoside recommended for use in children (46). The primary cellular mechanism of action of digoxin is inhibition of sarcolemmal Na⁺–K⁺ ATPase activity, resulting in a slight increase in intracellular sodium concentration. This change in sodium concentration affects sodium–calcium

Figure 79.4. Association with age on the apparent plasma clearance (CL/F) of pantoprazole. Composite data were derived from four registration studies of the drug (Pantoprazole Study Numbers 331, 333, 334, and 337) conducted by the innovator company (Wyeth Pharmaceuticals Radnor, PA). The data reflect the ontogeny of CYP2C19, the cytochrome P450 isoform primarily responsible for pantoprazole metabolism. The circle illustrated within the square box represents one subject that had a CYP2C19 genotype predictive of a poor-metabolizer phenotype. This is denoted to illustrate that during the first months of life, CYP2C19 genotype–phenotype discordance (i.e., developmentally associated reductions of enzyme activity in patients with a CYP2C19 genotype predictive of an extensive metabolizer phenotype) is expected.

exchange activity, which subsequently increases intracellular calcium concentration and contractility. However, the increase in contractility is modest and may be imperceptible in the nonfailing heart. In addition to this direct myocardial effect, digoxin slows cardiac conduction and heart rate and alters the neurohormonal milieu in patients with heart failure.

Digoxin is readily absorbed from the gastrointestinal tract, and peak serum levels occur approximately 30 to 90 minutes after an oral dose. Because digoxin has a large apparent volume of distribution, therapy may be initiated with a loading dose. The loading dose (digitalization dose) is generally divided over 12 to 24 hours (half total loading dose initially, one-fourth 6 to 12 hours later, and one-fourth 12 to 24 hours after the initial dose). Administration of a loading dose is associated with a higher incidence of toxic effects, especially in newborns. Furthermore, digoxin is rarely (if ever) required in an emergency so it is reasonable in most cases to begin maintenance dose therapy without a loading dose. Digoxin is excreted by the kidneys with a half-life that changes with age. The half-life is approximately 20 hours in infants and 40 hours in older children, changes associated with developmental increases in renal function. The clearance of digoxin is directly related to renal function, and the dosage must be adjusted in patients with impaired renal function and in premature infants. Consequent to its long elimination half-life, digoxin may be given once daily in infants and children.

In patients with normal renal function and who receive age-appropriate maintenance doses of digoxin, routine monitoring of serum digoxin levels is not necessary. In addition, the presence of endogenous digoxin-like immunoreactive substances in infants may confound interpretation of serum digoxin concentrations performed by certain analytical methods in newborns. If drug concentration monitoring is performed, trough serum concentrations (as opposed to peak levels) should be used to guide adjustments in therapy. Because of the lack of relationship between higher serum levels and a greater therapeutic effect, the target serum digoxin levels should range between 1 and 2 ng/mL. The major indication for obtaining a serum digoxin concentration is in cases of known or suspected digoxin toxicity. This occurs most commonly in cases of accidental overdose and in complicated patients with renal failure and/or those taking medications that may interfere with digoxin clearance.

The primary indication for digoxin therapy in children is heart failure with systemic ventricular dysfunction. However, no randomized, prospective, controlled clinical trials of digoxin have been performed in this population. Therapeutic recommendations are therefore based largely on inferences drawn from adult studies and animal experiments. The use of digoxin in infants with a large left-to-right shunt is controversial. Most infants with intracardiac left-to-right shunts have apparently normal systolic ventricular function and likely do not benefit from a positive inotropic agent. Manipulation of loading conditions with diuretics is a more rational approach and should be used initially. However, some patients may benefit from the reduction in heart rate mediated by digoxin. Digoxin exerts important neurohormonal modulating effects in adult patients with congestive heart failure which may be of benefit, even in the absence of measurable objective changes in cardiac function. The neurohormonal effects of digoxin have not been adequately studied in infants and children.

Digoxin has a narrow therapeutic index and consequently, a high potential for producing toxicity. Common signs and symptoms of systemic toxicity in adults (anorexia, vomiting, visual disturbances, and CNS disturbances) may be difficult to recognize in infants. Digoxin toxicity should be suspected in any infant receiving the drug who presents with apathy toward feeding or feeding intolerance. Drugs that may predispose to digoxin toxicity include diuretics (hypokalemia)

and amiodarone (reduced elimination of digoxin). Cardiac toxicity in infants often results in second- or third-degree atrioventricular block with resulting bradycardia, but almost any type of arrhythmia can be produced by digoxin toxicity. Prolongation of the PR interval is an expected digoxin effect and is not a sign of toxicity. Treatment of acute digoxin toxicity requires hemodynamic and ECG monitoring, temporary cardiac pacing if necessary, normalization of serum potassium levels, and antiarrhythmic drug therapy. In cases of life-threatening arrhythmias, specific Fab antibody fragments should be administered intravenously.

ADRENERGIC AGONISTS

The cardiac and vascular responses to adrenergic agonists are mediated by specific receptors (47,48). Although grossly oversimplified, the heart contains mainly β_1 -, the lungs β_2 -, and the vasculature both β_2 - and α -adrenergic receptors. Stimulation of β_1 -adrenergic receptors in the mature heart increases rate, contractility, relaxation, and conduction. These events are mediated by G-protein-coupled stimulation of adenylyl cyclase, generation of cAMP, activation of cAMP-dependent protein kinase, and phosphorylation of key regulatory proteins involved in intramyocellular calcium regulation. Stimulation of β_2 -adrenergic receptors in the lungs produces bronchodilation and modest pulmonary vasodilation. Systemic vasoconstriction results from activation of α -adrenergic receptors. In contrast to most of the vascular bed, skeletal muscle vasculature contains β_2 -adrenergic receptors that promote vasodilation when activated. Dopaminergic receptors in the splanchnic and renal vascular beds produce vasodilation in response to dopaminergic agonists.

Maturation changes in the receptor-effector and signal transduction pathways result in age-related variability in responsiveness to adrenergic agonists (49–51). Loading conditions, volume status, and responsiveness of the peripheral vasculature can also influence the responses to these agents, especially in critically ill infants and children. Adrenergic agonists undergo rapid biotransformation and consequent to their very short elimination half-life, are administered by continuous intravenous infusion. The dose (infusion rate) must be carefully titrated with appropriate clinical and hemodynamic monitoring. Comparison of the relative effects on β -, α -, and dopaminergic receptor subtypes for various drugs is presented in Table 79.7.

TABLE 79.7 Effects of Agonists on Adrenergic Receptor Subtypes

Drug	Predominant Agonistic Effects
Dopamine	$\beta_1 = DA_1 > \alpha$
Dobutamine	β_1
Epinephrine	$\beta_1 = \beta_2 = \alpha$
Fenoldopam	DA_1
Phenylephrine	α
Norepinephrine	$\beta_1 = \alpha$
Isoproterenol	$\beta_1 = \beta_2$

Dopamine

Dopamine is an endogenous precursor of norepinephrine with direct cardiac β_1 -adrenergic agonist effects. In addition, dopamine indirectly stimulates β_1 -receptors by promoting the release of norepinephrine from presynaptic sympathetic nerve terminals within the myocardium. Unlike the other related catecholamines, dopamine exhibits specific dopaminergic receptor agonism (dopamine DA_1 receptor agonist). Dopamine has little or no effect on β_2 -adrenergic receptors, but at higher concentrations, it stimulates α_1 -adrenergic receptors. At low to moderate doses, the major action of dopamine is to increase contractility (β_1 -effect) and to dilate the renal vascular bed (DA_1 effect). At higher rates of infusion, α_1 -receptor stimulation (vasoconstriction) becomes more pronounced and the renal vasodilating effect is overcome.

Dopamine has gained considerable popularity for use in the acutely ill infant or child with cardiac dysfunction from any etiology (52–54). Low to moderate doses are thought to incur an additional advantage by increasing renal blood flow and maintaining urine output, although this has not been conclusively proven. At conventional doses, dopamine has little effect on pulmonary vascular resistance. High rates of infusion may increase systemic vascular resistance, induce sinus tachycardia, and provoke arrhythmias and, in critically ill patients with circulatory insufficiency, can result in peripheral gangrene. The clearance of dopamine is reduced in the presence of significant hepatic and/or renal compromise and the drug is not chemically stable when mixed with alkaline solutions.

Fenoldopam

Like dopamine, fenoldopam is a selective DA_1 agonist, but in contrast, fenoldopam is more potent than dopamine and does not stimulate α - or β -adrenergic receptors at conventional dosages. This pharmacologic profile results in dilation of the renal and splanchnic beds, increased renal blood flow and glomerular filtration rate, and diuresis. Fenoldopam is used primarily for treating hypertension in adults, but some centers have used intravenous fenoldopam in infants and children in an effort to promote diuresis (55,56). Potential advantages of fenoldopam include rapid titration and few side effects beyond excessive hypotension. However, the limited published results in oliguric infants immediately after cardiac surgery do not provide compelling evidence for a dramatic benefit from fenoldopam infusion. Additional prospective studies are needed to determine the role of fenoldopam in the management of acutely ill infants and children with heart disease.

Dobutamine

Dobutamine is a racemic mixture with complex actions involving α - and β -adrenergic receptors. The net response to conventional dosages in adult patients is that of β_1 -agonism with relatively little effect on β_2 -receptors, α -receptors, or DA_1 receptors. The usual pharmacodynamic response to dobutamine in children is an increase in contractility and cardiac output with minimal effects on pulmonary vascular resistance or heart rate. Systemic vascular resistance may decline because of improved cardiac output. In contrast to dopamine, dobutamine does not dilate the renal vascular bed. Dobutamine is often selected in situations for which the primary goal of therapy is to improve ventricular contractility (48,53).

Dobutamine may be administered as a single drug or as an adjunct to the infusion of other agents. Wide variability in drug clearance and in hemodynamic responses requires individual titration of dobutamine therapy, especially in infants. As the dosage increases, dobutamine may adversely increase heart

rate and myocardial oxygen demand. However, it appears to be less arrhythmogenic than the other sympathomimetic amines.

Epinephrine

Epinephrine is produced by the adrenal medulla and has extremely potent effects on α - and β -adrenergic receptors. At low concentrations, the predominant effects include increased heart rate, contractility, and systolic blood pressure due to β_1 -adrenergic stimulation. As the dose increases, diastolic blood pressure may decline slightly due to β_2 -adrenergic effects in the peripheral vasculature. At higher doses, α -adrenergic effects become prominent and pronounced vasoconstriction occurs.

The major indication for epinephrine is cardiovascular collapse associated with low cardiac output that is refractory to dopamine and/or dobutamine (47,48). Epinephrine must be infused cautiously with careful hemodynamic monitoring. The initial infusion rate should be at the lower end of the recommended dosage and then gradually increased as needed. The major life-threatening toxic effect of epinephrine is the induction of ventricular arrhythmias. Epinephrine increases myocardial oxygen requirements because of its prominent inotropic and chronotropic effects. High doses may produce myocardial ischemia, especially in cases involving either coronary artery anomalies or significant ventricular hypertrophy. Tissue ischemia can occur because of peripheral vasoconstriction, especially with high rates of infusion.

Norepinephrine

Norepinephrine has β_1 - and α -adrenergic agonist effects, but in contrast to epinephrine and isoproterenol, it does not stimulate β_2 -receptors (at conventional concentrations). Infusion of norepinephrine increases systolic and diastolic blood pressure, systemic vascular resistance, and contractility. Heart rate is largely unaffected. The prominent α -adrenergic effects of norepinephrine result in systemic vasoconstriction and reduced renal perfusion leading to reductions in urine output.

Norepinephrine is rarely used as a positive inotropic agent because of significant elevation of systemic vascular resistance, reduction in renal blood flow, and increased myocardial oxygen demand. Norepinephrine may be useful in gravely ill patients with cardiovascular collapse associated with profound peripheral vasodilation, such as hyperdynamic septic shock. Some infants exhibit little vascular tone following cardiopulmonary bypass surgery and norepinephrine may be helpful temporarily in supporting the systemic blood pressure. Adverse effects of norepinephrine include arrhythmias and tissue ischemia secondary to extreme vasoconstriction.

Isoproterenol

Isoproterenol is a synthetic catecholamine with potent non-selective β -adrenergic agonism and no significant effect on α -adrenergic receptors (47). Isoproterenol increases cardiac contractility and heart rate (β_1 -effect) and reduces systemic vascular resistance due to dilation of skeletal muscle, renal, and splanchnic beds (β_2 -effect). The drug is a potent bronchodilator and thus, may be particularly beneficial in patients with pulmonary disease and bronchoconstriction.

Bradycardia caused by atrioventricular block or sinus node dysfunction is probably the most common indication for isoproterenol in young infants. These patients may be managed temporarily by infusing isoproterenol until pacing can be instituted (either a temporary pacing catheter or a permanent

pacemaker). Although isoproterenol increases myocardial contractility and therefore increases cardiac output, this agent causes a much greater increase in heart rate than other adrenergic drugs. Since many infants with low cardiac output are already tachycardic, isoproterenol is used rarely.

Phenylephrine

Phenylephrine stimulates α_1 -adrenergic receptors and has relatively little effect on other adrenergic receptors. The hemodynamic effects of phenylephrine are related primarily to vasoconstriction and increased systemic vascular resistance. There may be a reflex decrease in heart rate. Administration of phenylephrine is indicated in conditions such as septic shock where the primary goal of therapy is to promote vasoconstriction. Phenylephrine has been used acutely during hypercyanotic episodes in patients with tetralogy of Fallot to increase systemic resistance, reduce the right-to-left shunt, increase pulmonary blood flow, and thereby improve systemic oxygenation.

PHOSPHODIESTERASE INHIBITORS

A family of phosphodiesterase enzymes with distinct activities and subcellular distributions controls the degradation of intracellular cAMP (and cGMP). Drugs that selectively inhibit cAMP phosphodiesterase activity increase the activation of protein kinase A, resulting in a positive inotropic effect in mature myocardium. Maturation of the phosphodiesterase system in human myocardium has not been characterized, but virtually every immature mammalian species studied exhibits little or no positive inotropic response to cAMP-specific phosphodiesterase inhibitors such as milrinone (41). Despite these observations, milrinone has gained widespread usage in the pre- and postoperative management of infants and children with ventricular dysfunction (48,57–59). However, whether the apparently beneficial hemodynamic responses are primarily due to increased contractility or to pulmonary and systemic vasodilation remains unclear.

Milrinone

Milrinone is a relatively selective inhibitor of type 3 cAMP-phosphodiesterase that is used in the postoperative period following cardiac surgery and in children with low cardiac output and ventricular dysfunction. Milrinone has lower clearance in infants than in older children and the dose must be adjusted accordingly. Milrinone is generally well tolerated and is not arrhythmogenic. Side effects include hypotension due to vasodilation (especially at higher doses) and thrombocytopenia.

CALCIUM-SENSITIZING AGENTS

Positive inotropic drugs that act via the cAMP–protein kinase A pathway (e.g., β_1 -adrenergic agonists, type 3 phosphodiesterase inhibitors) have side effects and inherent limitations that may be avoided by drugs that increase the sensitivity of the myofilaments to calcium. Many calcium-sensitizing agents have been developed but the drug that appears to hold the most promise is levosimendan (48,60–62). Levosimendan binds to troponin C and improves the efficiency of contraction without a requisite increase in either cAMP or intracellular calcium. Although not yet approved by the Food and Drug Administration, studies in adults suggest that levosimendan may be of

value as an adjunct or alternative to conventional inotropic agents in patients with refractory heart failure and systolic dysfunction. The published experience with levosimendan in children is quite limited and additional studies are necessary to determine the safety and efficacy in pediatric patients with depressed cardiac function.

DIURETICS

Diuretics remain a mainstay of therapy for heart failure and hypertension (59,63). However, diuretics do not improve the neurohormonal alterations that contribute to the heart failure syndrome. Aggressive diuresis can actually promote activation of the sympathetic nervous system and the renin–angiotensin–aldosterone system. Hypovolemia, decreased renal blood flow, reduced glomerular filtration rate, or sodium depletion may reduce diuretic efficacy. Given the array of drugs available, it is helpful to classify diuretics according to their predominant site of action within the nephron (see below). Relative potency and adverse effects vary among the different classes.

Loop Diuretics

These agents are potent diuretics and have been widely used in children for a variety of indications. The most commonly used drug is furosemide, but ethacrynic acid and bumetanide are also available. Loop diuretics inhibit chloride–sodium–potassium cotransport in the thick ascending limb of the loop of Henle. This reduces reabsorption of chloride, sodium, and potassium and increases net excretion of free water.

Furosemide

Furosemide increases renal blood flow, enhances renin release, and reduces renal vascular resistance. It has diuretic and non-diuretic pulmonary effects and appears to reduce pulmonary transvascular fluid filtration. The primary indications for furosemide in children with heart disease include acute and chronic management of congestive circulatory states and diuresis following cardiac surgery. Furosemide may be administered orally or intravenously. The drug is primarily excreted unchanged by the kidneys and the dosage must be adjusted in renal failure or in infants with immature renal function. Consequent to developmentally associated reductions in glomerular filtration rate, the plasma elimination half-life of furosemide in preterm infants is approximately 20 hours, as compared with 8 hours in term infants and 1 hour in adults. Likewise, the plasma clearance of furosemide is reduced in all patients with significant reductions in renal function; a scenario that also can lead to reduced diuretic response.

Adverse effects of furosemide include excessive contraction of extracellular volume, electrolyte imbalances, and ototoxicity. The risk of ototoxicity increases if renal dysfunction is present or if other ototoxic medications are administered concomitantly (such as aminoglycosides). Hyponatremia in older patients with congestive heart failure is generally due to excess total body water. However, in premature and term newborn infants with limited sodium intake, chronic or excessive use of furosemide may promote excessive sodium excretion and contribute to hyponatremia. Hypokalemia is a relatively common side effect of therapy with loop diuretics, and serum potassium should be monitored, especially in the acute care setting. Potassium supplementation is often required in the perioperative period for infants with significant congenital heart disease. Hypochloremic metabolic alkalosis is a common occurrence with furosemide therapy and if severe, chloride

supplementation is required. Hypocalcemia and hypomagnesemia are usually not significant clinically, but one must be alert to these potential complications, especially in the immediate postoperative period.

Ethacrynic Acid

Ethacrynic acid is occasionally used acutely in the management of patients with significant or refractory volume overload. Generally, ethacrynic acid is reserved for use in children who do not respond adequately to furosemide. The indications and toxic effects of ethacrynic acid are otherwise comparable to those described for furosemide.

Bumetanide

Bumetanide is generally reserved for use in patients who have not responded adequately to conventional diuretic regimens. Bumetanide can be administered orally or intravenously. In contrast to furosemide, bumetanide is partially metabolized in the liver with approximately 50% excreted unchanged in the urine. Thus, the dosage may need to be reduced in patients with clinically significant hepatic and/or renal dysfunction. The indications and potential complications are similar to those described for furosemide.

Thiazide Diuretics

Thiazides inhibit sodium and chloride transport in the distal convoluted tubule of the nephron. Thiazide diuretics have been available for many years and there is broad experience with these agents. Hydrochlorothiazide and chlorothiazide are the primary drugs in this class used in children with cardiovascular disease. They are close structural analogs with similar mechanism of action, diuretic efficacy, and side effects. The main differences relate to dosage, absorption, and excretion. Following oral administration, a diuretic effect is generally noted within 60 minutes and may persist as long as 12 to 24 hours. Hydrochlorothiazide is more potent than chlorothiazide. A thiazide diuretic is generally used for outpatient management of a chronically congested circulatory state, but may also be useful in the inpatient setting for patients with more advanced heart failure. In this situation, they may be used in combination with a loop diuretic and/or a potassium-sparing agent. Adverse effects of thiazides include hypokalemia, hyperuricemia, and hypercalcemia. Nonrenal effects of thiazide diuretics that have been described in older patients and adults include carbohydrate intolerance and adverse effects on plasma cholesterol and triglycerides. The extent and implications of potential disturbances in cholesterol, lipoproteins, and triglycerides have not been determined in young children.

Metolazone

Metolazone is a sulfonamide derivative that blocks sodium reabsorption in the distal and proximal convoluted tubule. It exhibits several thiazide properties although it does not have a classic thiazide structure. In general, metolazone is reserved for short-term treatment of edematous states that are resistant to conventional therapy with loop diuretics or thiazides. The combination of metolazone and furosemide can be synergistic and promote marked diuresis (with associated electrolyte loss). Metolazone is given orally once a day or every other day. The major adverse effects of metolazone include significant volume depletion and severe electrolyte disturbances.

Potassium-Sparing Diuretics

Spironolactone is the prodrug of canrenone, and therefore, bioactivation is required for drug action. The drug competitively inhibits aldosterone at the distal tubule and thus reduces potassium loss in the urine. The diuretic effect of spironolactone is relatively weak compared with the loop or thiazide diuretics. In most cases, it is used in combination with either furosemide or hydrochlorothiazide predominantly for its potassium-sparing effects. The major adverse effect of spironolactone is hyperkalemia, which, in most patients, is not a significant problem in the absence of excessive potassium intake (e.g., when coadministered with a potassium supplement), renal dysfunction, or hepatic dysfunction. Caution is required if spironolactone is used in combination with an angiotensin-converting enzyme (ACE) inhibitor because of the propensity for hyperkalemia. Similarly, if coadministration of a potassium supplement is necessary, serum potassium levels should be monitored carefully.

VASODILATORS

Many vasodilators are available that encompass a broad spectrum of mechanisms, primary sites of action, efficacy, and toxicity (59,64,65). The major indications for the use of vasodilators in children with heart disease are impaired ventricular function, pulmonary hypertension, aortic valve regurgitation, and systemic hypertension. The selection of a specific drug depends upon the primary goal of therapy, underlying or associated conditions, and whether or not the treatment is acute or chronic in nature. One approach to classifying vasodilators groups the drug classes according to their major mechanism of action (Table 79.8). Knowledge of the mechanism of action of a given drug provides a framework for understanding the pharmacology and therapeutic applications. Another method is to group drugs according to their predominant site of action (predominately venous, arteriolar, or balanced; Table 79.8). Depending on the therapeutic goals, one may select an agent that has predominant effects on venous capacitance, arteriolar resistance, or both.

Nitric Oxide–Modifying Drugs

Relaxation of vascular smooth muscle by drugs in this class is mediated by nitric oxide. Nitric oxide activates guanylyl

TABLE 79.8 Vasodilator Mechanisms and Sites of Action

Predominant Mechanism	Drug Examples	Predominant Site of Action
Nitrovasodilator	Nitroglycerin	Venous
Calcium channel antagonist	Nifedipine	Arteriolar
ACE inhibitor	Captopril	Mixed
Angiotensin receptor blocker	Losartan	Mixed
Natriuretic peptide	Nesiritide	Mixed

cyclase, resulting in increased formation of cGMP in vascular smooth muscle cells and activation of cGMP-dependent protein kinase. The net effect is relaxation of vascular smooth muscle.

Nitroglycerin

Nitroglycerin relaxes smooth muscle in the cardiovascular, respiratory, and gastrointestinal systems. At the usual therapeutic concentrations, the predominant site of action is the venous vascular bed. Nitroglycerin therefore acts principally to increase venous capacitance, promoting a reduction in atrial and ventricular filling pressures. Nitroglycerin has been largely replaced by other agents, but is sometimes administered after cardiac surgery. At low doses, there is little effect on systemic vascular resistance, systemic arterial pressure, or heart rate. However, higher doses can produce arteriolar dilation with hypotension and reflex tachycardia. Nitroglycerin is rapidly metabolized in the liver and must be given by continuous infusion. Nitroglycerin is a potent vasodilator that must be used with appropriate hemodynamic monitoring. Patients with decreased intravascular volume (low preload) may respond adversely to nitroglycerin because a further decline in filling pressure may significantly reduce cardiac output. Overdose causes hypotension and tachycardia, which respond quickly to a reduction in dose or cessation of the infusion.

Nitroprusside

Nitroprusside is an extremely potent vasodilator that reduces systemic and pulmonary vascular resistance and increases venous capacitance. It is used for treating hypertensive emergencies consequent to its potency, rapid onset of action, and titratable effects. Nitroprusside is occasionally administered to pediatric cardiac surgical patients in the immediate postoperative period. In addition, it may be effective acutely in children with left ventricular dysfunction and low cardiac output. With proper monitoring and dosing, nitroprusside appears to be safe and effective in neonates.

Nitroprusside is rapidly metabolized to thiocyanate and cyanide. While the precise relationships between cyanide or thiocyanate concentrations in plasma or red blood cells and clinical toxicity are not entirely clear, potential toxicity should be considered in patients with renal dysfunction who are receiving prolonged infusions of nitroprusside. Because of the rapid onset of action and rapid metabolism, the desired hemodynamic effect can be achieved by careful dose titration. The major adverse effects of nitroprusside are a direct extension of its powerful vasodilator activity. Careful hemodynamic monitoring is imperative in order to avoid significant hypotension. Due to limited stability and photodegradation, nitroprusside solutions must be freshly prepared before use and protected from light.

Pulmonary Vasodilators

Nitric Oxide

Nitric oxide is a gas that is administered via inhalation. This agent produces pulmonary vasodilation without affecting the systemic vasculature. Nitric oxide plays a central role in the management of infants with persistent pulmonary hypertension of the newborn (66,67). This agent is also beneficial in the perioperative period for infants and children with pulmonary arterial hypertension associated with congenital heart disease (48). Assessment of the response includes evaluation of systemic oxygenation and pulmonary artery pressure.

Echocardiography may be helpful in assessing pulmonary artery pressure noninvasively. Methemoglobin levels should be monitored regularly in patients receiving high concentrations or prolonged therapy.

Sildenafil

Sildenafil is a potent and selective inhibitor of cyclic nucleotide phosphodiesterase type 5, the predominant isoform involved in degradation of cGMP in the lung vasculature. Inhibition of this phosphodiesterase results in pulmonary vasodilation and will also increase the efficacy of inhaled nitric oxide (48,68,69). Sildenafil can be administered enterally, intravenously, or as an aerosol but most of the published experience in infants and children has been with the oral and intravenous forms. Orally administered sildenafil has been shown to be effective in treating persistent pulmonary hypertension in newborns and is well tolerated. However, given the lack of a proprietary liquid formulation of the drug, the potential exists for alterations in the oral bioavailability of sildenafil as a result of improperly constructed extemporaneous formulations. The primary use of sildenafil in children with cardiac disease is for patients with acute or chronic pulmonary hypertension following cardiac surgery. It has also been used in older children and adolescents with primary pulmonary hypertension.

α -Adrenergic Receptor Antagonists

Phentolamine

Phentolamine is a competitive nonselective antagonist of α -adrenergic receptors that blocks α_1 - and α_2 -receptors. Blockade of presynaptic α_2 -adrenergic receptors may contribute to the tachycardia and arrhythmias that occur at high doses of phentolamine. Administration of phentolamine to patients with low cardiac output produces a decrease in systemic vascular resistance with a resultant increase in cardiac output. Although phentolamine is classified as a mixed vasodilator, the effects on venous capacitance are minimal compared with other mixed vasodilators. Phentolamine reduces pulmonary vascular resistance and pulmonary arterial pressure. Experience with phentolamine in children is limited to short-term intravenous administration. In general, phentolamine is effective and well tolerated in infants and children. Adverse effects include significant sinus tachycardia, arrhythmias, and excessive hypotension.

Calcium Channel Antagonists

Calcium channel antagonists block the opening of calcium channels in vascular smooth muscle, thereby promoting vasodilation. However, these drugs also block L-type calcium channels in the heart. Newborns are more sensitive to the negative inotropic effects of calcium channel blockers than are older children, and intravenous administration of calcium channel blockers in infants has been associated with cardiovascular collapse. These drugs must be avoided or used with extreme caution in neonates and infants.

Calcium channel antagonists are categorized into three major chemical classes: phenylalkylamines (e.g., verapamil), dihydropyridines (e.g., nifedipine), and benzothiazepines (e.g., diltiazem). Drugs of the dihydropyridine class exhibit the most pronounced vasodilation and should be selected if that is the primary goal of therapy. Most of the published pediatric experience with dihydropyridines is limited to nifedipine, but the clinically important differences among the various drugs in this chemical class are slight. In young infants, nifedipine is used primarily to treat pulmonary hypertension associated

with bronchopulmonary dysplasia. Oral verapamil is occasionally used in older infants with arrhythmias or hypertrophic cardiomyopathy.

Angiotensin-Converting Enzyme (ACE) Inhibitors

ACE inhibitors play a central role in the management of systemic hypertension and congestive heart failure in adults. However, relatively few randomized prospective clinical trials have been performed using ACE inhibitors in infants and children. Despite the relative paucity of information from well-controlled clinical trials, anecdotal reports, case series, and clinical experience suggest that the ACE inhibitors have beneficial effects in children with hypertension and heart failure, especially in the short term (64,70,71).

The result of inhibiting ACE is reduced conversion of angiotensin I to angiotensin II, a potent vasoconstrictor. In addition, ACE inhibitors reduce the degradation of vasodilatory bradykinins and diminish production of aldosterone. Hemodynamic effects of ACE inhibitors include a reduction in systemic vascular resistance and systemic blood pressure. Long-term studies of ACE inhibitors in adults with heart failure demonstrate significant improvements in survival, reduction in hospitalizations, and improvements in quality of life. The beneficial effects and safety profile of ACE inhibitors have prompted the recommendation that these drugs be prescribed for asymptomatic adults with documented left ventricular dysfunction.

Several ACE inhibitors are commercially available in the United States. These drugs are similar with regard to their mechanism of action but differ slightly in their metabolism and pharmacokinetics. Most of the published experience in children is with captopril, enalapril, and lisinopril.

Captopril

Captopril (as with all ACE inhibitors) is a mixed or balanced vasodilator that reduces systemic vascular resistance and increases venous capacitance. In children with congestive heart failure, these effects result in increased cardiac output and a reduction in cardiac filling pressures. Pulmonary vascular resistance generally declines and heart rate is usually minimally affected. Mild-to-moderate diuresis may occur because of increased renal blood flow and reduced aldosterone formation. Captopril is administered orally and peak plasma concentrations generally occur 1 to 2 hours after a single oral dose. Its plasma elimination half-life is relatively rapid with values ranging between 2 and 3 hours. Approximately 50% is excreted in the urine unchanged, and thus, captopril plasma clearance is reduced in patients with impaired renal function.

Captopril is used for the treatment of systemic hypertension and congestive heart failure in infants, children, and adolescents. It is generally well tolerated, but significant hypotension may occur in volume-depleted patients or in patients with extremely high basal renin activity. When starting captopril therapy for congestive heart failure in neonates and young infants, a low first dose is given and blood pressure should be monitored. If the drug is well tolerated, then the dosage can be escalated over a few days.

Adverse effects include neutropenia and proteinuria, especially in children with underlying renal disease. Less serious reactions include rash, taste impairment, and minor gastrointestinal disturbances. A dry nonproductive cough is a well-described feature of ACE inhibitor therapy in adults, but this does not seem to be a major problem in children. In general, potassium supplements and potassium-sparing diuretics should not be administered concomitantly to patients receiving captopril because of the risk of hyperkalemia. All ACE

inhibitors are contraindicated in pregnancy because of the association with fetal demise and major congenital malformations. Thus, captopril must be used with appropriate caution in adolescent females and should be immediately discontinued if pregnancy occurs.

Enalapril and Lisinopril

The mechanism of action, hemodynamics, and clinical indications for enalapril and lisinopril are similar to those described above for captopril. These drugs have a slower onset of action and longer half-life than captopril. Enalapril and lisinopril can be administered once daily, which may improve compliance compared to captopril. Enalapril is a prodrug that must be de-esterified to form the active agent, enalaprilat. Enalaprilat is commercially available for parenteral administration. The overall incidence of side effects due to enalapril and lisinopril appears to be lower than that reported for captopril.

Angiotensin Receptor Blockers

Angiotensin (AT) receptors exist as distinct subtypes that couple AT with specific intracellular responses. Because local tissue production of AT may occur that is not ACE-dependent, more complete local inhibition of the AT pathway can theoretically be achieved by direct blockade of AT receptors. Several selective AT₁ receptor blockers are commercially available and have been studied in adults with heart failure and/or hypertension (72). The prototype is losartan. Experience with these agents in infants and children is limited at present. However, based on theoretical considerations and results obtained from clinical trials in adults, these agents may prove to be useful in the pediatric population.

In addition to blocking AT₁ receptors, losartan also blocks transforming growth factor (TGF- β) activity. This effect has been shown experimentally to be beneficial in animal models of muscular dystrophy and connective tissue disorders (73,74). Use of these agents in pediatric patients with connective tissue disease such as Marfan and Loeys-Dietz syndromes and Duchenne muscular dystrophy is a subject of current investigation.

ALDOSTERONE RECEPTOR ANTAGONISTS

Activation of the renin-angiotensin system with increased synthesis of aldosterone is a hallmark of the heart failure syndrome. Aldosterone plays an important role in promoting the abnormal collagen production and interstitial fibrosis that occurs in chronic heart failure. Therapy with an ACE inhibitor blocks angiotensin II formation and reduces aldosterone production. However, aldosterone synthesis may "escape" despite the appropriate use of an ACE inhibitor (72). An escape of aldosterone production in adult patients is associated with sodium retention, potassium and magnesium loss, excessive myocardial collagen production, ventricular hypertrophy, myocardial norepinephrine release, endothelial dysfunction, and a decrease in serum high-density lipoprotein cholesterol. Administration of aldosterone antagonists, such as spironolactone or eplerenone, to adult patients with heart failure treated with conventional therapy results in increased diuresis and symptomatic improvement (72,75). Spironolactone has been used for years as a potassium-sparing diuretic in infants and children with heart failure, but it has not been extensively studied in this

patient population. Whether additional benefit is derived from inhibiting the other effects of aldosterone in pediatric patients remains to be determined.

HORMONES

Nesiritide

Nesiritide is a recombinant B-type natriuretic peptide that has been studied in adults with heart failure. It is administered intravenously and produces vasodilation, increases glomerular filtration rate, inhibits renal sodium reabsorption, and promotes diuresis. Despite considerable investigation in the adult population, the role and efficacy of nesiritide is controversial. Several studies in children suggest nesiritide may increase urine output and reduce levels of neurohormonal markers of heart failure. Some centers use nesiritide acutely for infants with low cardiac output following cardiac surgery and for infants with severely depressed cardiac function due to cardiomyopathy (48,76,77). Additional studies are needed to determine the safety and efficacy of nesiritide in pediatric patients with heart disease.

Thyroxine and Triiodothyronine

Thyroid hormone secretion is reduced in critically ill adults and children following cardiac surgery. These changes in thyroid hormone levels are referred to as “non-thyroidal illness syndrome” and generally have not been thought to represent true hypothyroidism. However, this concept is controversial and some authorities suggest that these patients may have acquired true central hypothyroidism as a consequence of their critical illness or surgical procedure. Some centers administer either thyroxine or triiodothyronine in the postoperative period if thyroid-stimulating hormone is elevated, circulating thyroid hormone levels are reduced, and the child has evidence of low cardiac output (78). However, relatively little published information exists regarding the safety, efficacy, and long-term effects of thyroid hormone administration to children in the early postcardiac surgery period. Additional studies are required to determine if thyroid hormone therapy has a beneficial role in this setting.

Vasopressin

Vasopressin is a potent vasoconstrictor that acts directly on the vasculature via V1 receptors and indirectly by potentiating the vasoconstrictor effects of catecholamines. Cardiopulmonary bypass produces a systemic inflammatory response that can result in low cardiac output and vasodilatory shock. The first line of therapy in this setting is infusion of catecholamines such as dopamine or norepinephrine. However, shock persists in some infants and children despite maximal supportive therapy. This clinical syndrome mimics that seen in patients with septic shock, which has been associated with depressed levels of vasopressin in adults and children. In contrast to catecholamines, the responses to vasopressin are preserved in the presence of acidosis or hypoxia. Based on results from studies demonstrating a beneficial effect of vasopressin infusion in patients with vasodilatory septic shock, several investigators have administered vasopressin to infants with vasodilatory shock following cardiopulmonary bypass (79,80). In general, the reported results are favorable and it appears that vasopressin can be an effective adjunct to more conventional therapy in this setting. However, additional

studies are required to more fully define the indications, safety, and efficacy of vasopressin treatment in children with heart disease.

β -ADRENERGIC RECEPTOR BLOCKERS

β -Blockers can be classified as first generation, nonselective for β_1 - and β_2 -blockade (e.g., propranolol); second generation with relative selectivity for β_1 -receptors (e.g., metoprolol and atenolol); and third generation drugs (selective or nonselective; e.g., carvedilol, and nebivolol). Furthermore, individual drugs differ with regard to the degree of important ancillary properties such as α -adrenergic receptor blockade, antioxidant activity, and intrinsic sympathomimetic activity (81,82). Because of these important differences, the various β -blockers are not interchangeable. Published experience in pediatric patients is limited and therapy for children is derived from adult experiences. The most commonly used β -blockers in infants are propranolol and esmolol. These drugs are also used in older children and adolescents, but in these older age groups, drugs such as metoprolol, atenolol, and carvedilol are also used.

Propranolol

Propranolol was the first commercially available β -adrenergic blocker in the United States, and consequently, this is the drug in this class with the most widely published experience in pediatrics. Propranolol is available for oral or intravenous administration, but if intravenous β -blocker therapy is necessary, the short-acting β -adrenergic blocker, esmolol (see below) should be used because of the risk of hypotension and bradycardia from the intravenous administration of propranolol.

Propranolol is used in infants for management of supraventricular tachycardia, some forms of ventricular arrhythmias, treatment of long QT syndromes, and hypertrophic cardiomyopathy. In the past, it was sometimes used in an attempt to reduce the frequency and severity of hypercyanotic episodes in infants with tetralogy of Fallot. Presently, most patients undergo surgical correction or palliation if hypercyanotic episodes occur. However, some infants with critical pulmonary stenosis may benefit from a short course of propranolol after relief of pulmonary valve stenosis until the infundibular hypertrophy improves.

Propranolol is well absorbed after an oral dose, although it undergoes extensive first-pass hepatic metabolism that reduces the bioavailability to approximately 30% to 40%. Class-dependent effects of β -adrenergic blockers include depression of contractility, atrioventricular block, bronchospasm, and sleep disturbances. Propranolol should be avoided if possible in infants with significant pulmonary disease because of the propensity for bronchoconstriction. While the chronic use of propranolol in infants appears to be safe and well tolerated, infants are at risk for developing hypoglycemia if their oral intake is restricted because of other illnesses or other conditions. Blood glucose should be monitored in infants receiving propranolol (or other β -adrenergic receptor blockers) who are unable to feed normally.

Esmolol

Esmolol is a β_1 -selective adrenergic blocker with a short plasma half-life (~5 to 10 minutes). The indications and precautions for esmolol are similar to those described above for propranolol. The major difference is that because of its rapid plasma clearance (and short elimination half-life), esmolol is administered by continuous intravenous infusion that can be easily titrated.

Generally, esmolol is used for short periods of time in acute care settings (i.e., cardiac catheterization laboratory, postoperative recovery unit, and neonatal intensive care nursery).

Metoprolol and Atenolol

Metoprolol and atenolol are relatively selective for β_1 -adrenergic receptors (this selectivity is lost at higher concentrations). Metoprolol is more lipid soluble than atenolol and has greater passage across the blood-brain barrier as compared to atenolol. Consequently, metoprolol may have greater CNS effects (dizziness, depression, sleep disturbances) than atenolol. Although fewer CNS effects occur with atenolol, the clinical implications in neonates and young infants are unclear. Metoprolol is metabolized more rapidly than atenolol and has a shorter plasma elimination half-life. Extended release preparations of metoprolol are available but are difficult to use in infants and small children consequent to inflexibility in the dosage form to permit weight-based (i.e., mg/kg) dosing. Atenolol has the advantage of requiring only once or twice daily administration because of a longer elimination half-life (8 to 10 hours). Flexibility in oral dosing of atenolol for young infants and children can be achieved via the extemporaneous formulation of a liquid preparation.

Carvedilol

Carvedilol is a third-generation β -adrenergic receptor blocker that blocks β_1 -, β_2 -, and α_1 -adrenergic receptors. In addition, it exhibits antioxidant, anti-inflammatory, and antiapoptotic activities. Results from a randomized controlled trial of carvedilol therapy in children with heart failure failed to show a beneficial effect of the drug on a composite measure of heart failure outcomes (83). However, event rates were lower than expected, the study population was heterogeneous, and the trial may have been underpowered. Furthermore, the improvement rate among placebo-treated patients was higher than predicted, and trough carvedilol concentrations in the blood were lower than expected (based on adult studies). Additionally, the high proportion of infants and toddlers may have impacted the overall results as this age group tends to have higher spontaneous improvement rates. Additional studies are necessary to define the potential role of carvedilol (and other β -adrenergic receptor blockers) in managing children with heart failure.

PROSTAGLANDIN E_1

Prostaglandin E_1 (PGE_1) is used to dilate the ductus arteriosus in newborns dependent upon a patent ductus arteriosus to maintain either pulmonary or systemic blood flow or to improve mixing (e.g., d-transposition of the great arteries). The common indications for PGE_1 therapy include pulmonary atresia, critical pulmonary stenosis, transposition of the great arteries, coarctation of the aorta, interrupted aortic arch, critical aortic stenosis, and hypoplastic left heart syndrome. Administration of PGE_1 should be strongly considered very early in the management of infants in whom a ductus-dependent cardiac defect is considered as part of the differential diagnosis, especially for infants with possible congenital heart disease born at a center without tertiary care cardiac services. In these cases, it is advisable to begin PGE_1 therapy before transport and continue the infusion until definitive delineation of the cardiac status can be accomplished. Early treatment can be lifesaving and conversely, withholding therapy can be disastrous if the ductus arteriosus closes in a patient with a ductus-dependent defect. Although not entirely benign, the potential benefits of PGE_1 administration outweigh its risks in this condition.

PGE_1 has a short half-life and must be given by continuous intravascular infusion. Because these infants are critically dependent upon the infusion for maintaining ductus patency, a reliable intravenous line is essential. Thus, the use of a central venous (umbilical venous) catheter is recommended whenever possible. Although the intravenous route is preferred, it can be given via an umbilical arterial catheter. The short elimination half-life of PGE_1 also results in rapid termination of effect when infusions are discontinued in infants found not to have ductus-dependent heart lesions. In addition to relaxing the ductus arteriosus, PGE_1 dilates the systemic and pulmonary vascular beds and may thereby cause hypotension. If the blood pressure falls, reduction of the rate of infusion is generally sufficient to restore the blood pressure. Another potentially serious adverse effect is apnea. Administration of a high dose or an inadvertent bolus of PGE_1 will likely induce apnea. Thus, whenever PGE_1 is administered, personnel and equipment necessary to support ventilation must be available. Infusion pumps with a continuous action should be used and the intravenous line containing the drug must not be flushed. Additional side effects include fever, irritability, edema, and cutaneous flushing.

ANTIARRHYTHMIC DRUGS

In contrast to older children and adults in whom catheter ablation has decreased the need for pharmacologic management of arrhythmias, drug therapy remains important in infants and young children because of the technical difficulties associated with ablation and device placement in this age group. Pharmacokinetics differ in infants compared to older children, and developmental changes in ion channels and the autonomic nervous system affect the responses to these agents. Despite these considerations, there is a paucity of information in young children from prospective trials and therapeutic approaches are extrapolated from studies in adults. Several antiarrhythmic agents are available, but only the most commonly used drugs in the pediatric population are presented in this chapter. Additional information on antiarrhythmic drugs is available in Chapter 18.

Children receiving antiarrhythmic agents must be monitored carefully because many of these agents have variable potential to produce arrhythmias (i.e., proarrhythmic effects) other than those being treated. Serial ECG examinations are helpful in evaluating changes in response to various agents that may be proarrhythmic. For those agents with defined serum concentration-effect profiles, therapeutic drug monitoring is recommended during their use to facilitate safe and effective treatment. It should be noted that while proarrhythmic effects are likely to occur soon after initiation of treatment, late effects for most drugs have been reported. The Vaughan Williams classification of antiarrhythmic medications describes antiarrhythmic actions and is used traditionally (84). However, the therapeutic utility of this classification scheme is somewhat limited from a clinical standpoint because several drugs have more than one effect, antiarrhythmic actions do not always correlate with efficacy, and some useful agents such as adenosine do not fit into this classification (85).

Class I Agents

A common feature of Class I antiarrhythmic agents is blockade of sodium channels. These drugs are further subclassified on the basis of other electrophysiologic effects.

Class IA (Procainamide)

The IA drugs decrease the upstroke velocity of the action potential by blocking sodium channels. This slows conduction

time in the atrial and ventricular muscle cells, His-Purkinje cells, and accessory atrioventricular pathways and decreases automaticity. These agents also block potassium channels. The PR interval is prolonged, the QRS duration is increased, and the QTc interval is prolonged. These agents are contraindicated in patients with long QT syndrome and should not be used with other drugs such as amiodarone that also prolong the QTc interval. While oral administration is common for chronic use of procainamide in adults, the drug is usually administered by the intravenous route in pediatric patients with careful monitoring of infusion-related hypotension. Procainamide can also cause mild depression of myocardial contractile function. The drug is also biotransformed via the polymorphically expressed enzyme *N*-acetyltransferase to *N*-acetylprocainamide (NAPA), an active moiety with Class III properties. The risk of proarrhythmia, especially *torsade de pointes*, is moderate and not related to serum drug concentrations.

Class IB (Lidocaine, Mexiletine, Phenytoin)

These drugs shorten action potential duration and the refractory period primarily in Purkinje fibers and in ventricular myocytes producing a decrease in automaticity. Cells in the sinoatrial and atrioventricular nodes and autonomic tone are minimally affected. The ECG may show a slight decrease in the QTc interval. Proarrhythmic effects are relatively uncommon with these agents. Lidocaine, the prototypical agent of this class, is given intravenously. High plasma concentrations are associated with depressed myocardial function and toxicity often causes drowsiness, disorientation, muscle twitching, and seizures. Mexiletine is available for oral administration and is used in some forms of congenital long QT syndrome because of its effects on sodium channels. Phenytoin is used rarely and is generally restricted to the treatment of ventricular arrhythmias associated with toxicity from digoxin and tricyclic antidepressant agents.

Class IC (Flecainide, Propafenone)

These agents markedly decrease the upstroke velocity of the action potential and decrease conduction. The PR interval is prolonged and QRS duration increases. Flecainide is a particularly effective inhibitor of abnormal automaticity and reentry within atrial and ventricular muscle and in accessory atrioventricular pathways. It has been used successfully to treat various arrhythmias including supraventricular tachycardia, persistent junctional reciprocating tachycardia, and ventricular tachycardia. The relatively high incidence of proarrhythmia, especially *torsade de pointes*, limits the use of flecainide in patients with structural heart disease. Flecainide is useful for treating infants with supraventricular tachycardia and structurally normal hearts who do not respond to β -adrenergic blocking agents and digoxin.

Propafenone blocks sodium channels but also has β -blocking effects and is a weak calcium channel antagonist. It is effective in controlling reentrant and automatic tachycardias but should be used with caution in patients with structural heart disease because of the risk of proarrhythmia.

Class II (Propranolol, Atenolol, Esmolol)

Drugs in this class are β -adrenergic blocking agents and have been discussed above in this chapter. These drugs indirectly decrease automaticity and slow atrioventricular conduction by virtue of blocking the effects of catecholamines. The slowing of AV conduction and suppression of premature beats that may initiate a reentrant circuit explain the efficacy of these agents in treating reentrant tachycardias.

Class III (Amiodarone, Sotalol)

Class III drugs block potassium channels and prolong the plateau of the action potential, but action potential upstroke velocity is not affected.

Amiodarone has broad and complex pharmacologic effects (86). In addition to blocking potassium channels, it also inhibits sodium and calcium channels. Action potential duration is increased and the effective refractory period is prolonged in atrial and ventricular muscle, Purkinje fibers, and accessory AV pathways. Amiodarone also has α - and β -blocking properties but does not depress myocardial function despite its decreasing automaticity. Changes in the ECG include sinus slowing, prolongation of the PR interval, minimal widening of the QRS complex, and prolongation of the QTc interval. Proarrhythmic responses are infrequent. Amiodarone has the potential to produce adverse reactions in multiple systems that include corneal microdeposits, hyper- or hypothyroidism, pulmonary interstitial fibrosis, hepatitis, peripheral neuropathy, and a slate-blue discoloration of the skin. These adverse reactions seem to be less common in pediatric patients than in adults. Baseline hepatic, renal, and thyroid function tests, ophthalmologic examination, and pulmonary function tests should be obtained before starting long-term therapy and then repeated every 6 months as long as the patient is taking amiodarone. Amiodarone can be administered intravenously for the acute management of a variety of arrhythmias in pediatric patients (86,87) and by this route, may cause hypotension. Amiodarone interacts with digoxin, phenytoin, and warfarin and the doses of these medications should be appropriately decreased and closely monitored when amiodarone is coadministered. Dronedarone is a newer derivative of amiodarone that appears to have a more favorable safety profile (88), but this drug remains to be studied in the pediatric population.

Sotalol is a nonselective β -adrenergic blocking agent at low doses but shows Class III activity at higher doses. The QTc interval increases in a dose-dependent manner. *Torsade de pointes* occurs in up to 10% of pediatric patients, usually within a few days of starting therapy. Close monitoring of the QTc interval on the ECG is recommended. Sotalol should not be administered with other drugs such as procainamide that also prolong the QTc interval.

Class IV (Calcium Channel Blockers)

Calcium channel antagonists are reviewed above in this chapter. Calcium channel blockers prolong refractoriness and conduction time. Dihydropyridines have much less effect on electrophysiologic properties and are not used for treating arrhythmias. Phenylalkylamines (e.g., verapamil) and benzothiazepines (e.g., diltiazem) are effective in managing supraventricular tachycardia and some forms of ventricular tachycardia, such as that originating from the right ventricular outflow tract. Administration of intravenous verapamil is contraindicated in patients <1 year of age because of the risk of precipitating cardiovascular collapse.

Digoxin

As denoted previously in this chapter, digoxin decreases action potential duration and effective refractory period. Additionally, digoxin increases vagal tone causing slowing of sinus node rate and decreased atrioventricular node conduction. The ECG shows sinus slowing, prolongation of the PR interval, mild depression of the ST segment, and mild flattening of T waves.

Digoxin is used primarily for its effect to inhibit atrioventricular conduction and is therefore used to decrease the rate

of ventricular response in atrial fibrillation, ectopic atrial tachycardia, and other refractory supraventricular tachycardias. Digoxin is also effective in all reentrant arrhythmias in which the atrioventricular node is involved in the reentrant circuit. However, digoxin should not be used on an outpatient basis in patients with Wolff-Parkinson-White syndrome because it may shorten the effective refractory period of the accessory pathway and thus allow very rapid ventricular response rates in patients with atrial fibrillation or flutter.

Adenosine

Adenosine is an endogenous nucleoside that is considered as first-line medical therapy to terminate supraventricular tachycardia by blocking conduction through the atrioventricular node (89). Adenosine has a very short elimination half-life and thus, it is administered as a rapid intravenous bolus injection. This will convert most reentrant tachycardias to sinus rhythm. The most common reason for failure of adenosine to convert a patient to sinus rhythm is probably poor administration technique (not given as a rapid bolus). If adenosine is not effective after three doses or it is effective but the tachycardia recurs immediately, there is no reason to continue repeating the dose. If adenosine does not terminate tachycardia, other modalities should be considered because the tachycardia may not involve the atrioventricular node. Adenosine administration may be diagnostic in that the transient induction of atrioventricular block allows flutter waves or P waves consistent with ectopic atrial tachycardia to be seen more easily on the ECG.

CONCLUSIONS

The effective pharmacotherapy of cardiac disease and disorders in pediatric patients requires not only drug selection based on the pharmacologic properties of a given drug but also consideration of how ontogeny can influence both the drug's pharmacokinetics and pharmacodynamics. While data pertaining to drug action in adults can be used to predict drug action in an infant or child, this may not be true for drug disposition given that the maturation of multiple pathways that contribute to drug clearance may not develop in synchrony. Employing the "tools" of clinical pharmacology such as therapeutic drug monitoring (i.e., to assess dose-concentration-effect relationships) and pharmacogenetics (i.e., to predict, based on genotype-phenotype relationships, increased likelihood for sub- or suprathreshold response with conventional drug dosing regimens) can do much to improve the safety and efficacy of cardiovascular drug treatment in pediatric patients.

 capillary malformations, 873
 fast-flow vascular malformations, 873–874, 976
 imaging of, 873
 lymphatic malformations, 872–873
 venous malformations, 867–868, 870f (*see also* Venous malformations)
 Vascular resistance
 cardiac catheterization and, 271–272
 changes at birth, 72, 73f
 Vascular response, hypnotic drugs and, 1078
 Vascular rings, 253, 253f, 759–760, 760t, 760t
 aortic arch anomalies, 759
 double aortic arch, 778–782
 mirror-image right arch, 766–767, 767f, 768f, 769f
 MRI, 233–234, 234f
 turbo spin echo, 234, 234f
 Vascular sheaths, 424
 Vasculitis, RF and, 1307
 Vasculogenesis, 61
 distal coronary development, 571
 Vasoactive medications, HLHS and, 1076
 Vasoconstrictor neuropeptide-containing nerves
 reactive pulmonary circulation, 1406, 1407f
 Vasoconstrictors, 494–495
 Vasodilating drugs
 cardiopulmonary bypass, 532
 pediatric heart transplantation, 1394
 Vasodilators, 492t, 495–497, 1676–1678, 1676t
 Vasopressin, 495, 1679
 cerebral blood flow, postnatal peripheral circulation, 76
 kidney and, 79
 Vasoreactivity testing, pulmonary arterial hypertension, 1450
 VAT. *See* Ventilatory anaerobic threshold
 VATER association, 624t, 634–635, 1579
 Vaughan-Williams classification
 action potential changes, 456f
 chaotic atrial tachycardia, 449, 450t
 VCS. *See* Ventricular conduction system
 VEC MRI sequence, blood flow analysis, 223–225
 Vectorcardiography, 373
 Vegetation formation
 antibiotic therapy, IE and, 1365
 endocarditis, 1365
 Velocardiofacial syndrome, 621t, 627–628
 Velocity-time integral (VTI), 131
 Vena caval injury, trauma and, 556
 Venoarterial extracorporeal membrane oxygenator (ECMO), HLHS and, 1079
 Venoatrial connections, 44
 Venous collateral vessels, angiogram, 279, 281f
 Venous connections
 cardiac malpositions, 1210
 univentricular atrioventricular connection, 1189
- Venous drainage, LSCV, 279
 Venous hum murmur, 92
 Venous hum, PDA, 731
 Venous malformations
 congenital phlebectasia, 868, 871f
 histological features of, 867
 intralesional venography, 868, 871f
 localized intravascular coagulation, 868
 macrocytic lymphatic malformation, 868, 872f
 MRI of, 867, 870f
 sclerotherapy, 868, 871f
 treatment of
 compression stocking for, 869
 extralesional extravasation, sclerosant, 871, 875f
 sclerotherapy, 869–870
 Venous murmurs, 92
 Venous oximetry, intravascular oxyhemoglobin monitoring, 486
 Venous systems, embryology, 840–845
 Venous valves, pulmonary atresia and intact ventricular septum, 940–941
 Ventilation measurements, 131–132
 Ventilation-perfusion scintigraphy
 pulmonary arterial hypertension (PAH), 1438
 Ventilatory anaerobic threshold (VAT), 120–121
 Ventilatory threshold (VT), 120–121
 Ventricle repair, 907–908
 Ventricles, 40–41, 40f, 1089
 anatomy, 1211
 base-apex characteristics, 4
 comparison of, 13f, 15
 general features, 4
 positions of, 42–43, 43f
 Ventricular aneurysm, 504
 MRI and, 228
 posttraumatic, 555
 Ventricular aneurysmectomy, ventricular aneurysm, 555
 Ventricular arrhythmias
 athletic screening and, 103, 104
 rTOE, 1476
 Ventricular assist device (VAD)
 adverse events, 539, 539t
 clinical criteria for, 538–539, 538f, 539f
 extracorporeal membrane oxygenation (ECMO), 1596
 implant in children, by era, 539–540, 540f, 541f
 implant, survival and, 539f
 pediatric patients, short-term VADs *v.* chronic pulsatile device, 539t
 pediatrics, 538–542
 Ventricular chambers, fetal cardiovascular system and, 645f, 646
 Ventricular conduction network, 359–361, 362f, 363f
 Ventricular conduction system (VCS)
 developmental aspects, 367, 367f
 Ventricular depolarization, 376f, 377
 Ventricular diastole, 188
 Ventricular dysfunction, late Fontan and, HLHS, 1085
 Ventricular failure, DMD and, 1279
 Ventricular fibrosis, 981–982
 Ventricular function
 quantitative evaluation, steps in, 215, 217–219
 SSFP and, 215, 218, 219
 Ventricular ischemia, myxomas, 1556
 Ventricular mass, in children, blood pressure and, 1528
 Ventricular morphology, 41
 myocardial, 1180, 1181 f
 univentricular atrioventricular connection, 1190–1191, 1192f
 Ventricular myocardium, morphology, 1190–1191, 1192f
 Ventricular out flow tracts (OFTs), 349
 Ventricular outflow
 tracts, fetal cardiovascular system and, 650f
 Ventricular outlet septum, malalignment defects of, 1117
 Ventricular output
 preferential pattern of, 70, 70f
